Stretch draw forming is done in three types of machines. In one type, the form block mounted on a hydraulic cylinder is pushed into the blank, which is held in tension by a pair of pivoting

grippers. In another type, the form block is fixed to the table, and the blank is drawn around it by a pair of grippers actuated by slides or a hydraulic cylinder. The third type of machine is a single-action hydraulic press equipped with a means of closing and moving a pair of grippers (see Fig. 7); a mating die is used instead of a form block. The hydraulic presses ordinarily used in stretch draw forming have capacities of 1800 to 7100 kN (200 to 800 tonf).

**Accessory Equipment.** Grippers and wiping shoes or rollers are made to conform to the rolled or extruded shape that is to be stretch formed. Jaws used for gripping sheet in stretch draw forming can be segmented or contoured to apply equal stretch to all parts of the sheet as it is formed. The vertical adapter shown in Fig. 5 is used with a rotary table; it is fastened to the hydraulic cylinder used for applying tension to the blank. The adapter allows wiper shoes, rollers, and grippers to move up or down as needed in order to accommodate work with bends in two or more planes. Lead screws or hydraulic cylinders position the grippers or wiping devices at the correct position for the forming operation (see Examples 5 and 6).

A yield detector and tension-control device (Fig. 6) provide a means of automatically applying the same amount of stress to every workpiece in a production lot. This is important with metals (for example, titanium) that have yield strength and tensile strength too close for ordinary control of tension for stretch forming (see the article "Forming of Titanium and Titanium Alloys" in this Volume). With this type of control, scrap in the stretch forming of titanium can be reduced to 2%.

The tension control uses two inputs in a null system for its output signal. One input comes from a load cell that gives a signal proportional to the stretch force on the workpiece. The other signal comes from a potentiometer that measures

**Fig. 2** Titanium alloy gas-turbine ring that was produced by compression forming. Dimensions given in inches

**Fig. 3** Stretch draw formed automobile roof. Dimensions given in inches

the elongation of the workpiece. As long as the signals are proportional, the metal is not stretched beyond its yield point, and the two inputs balance. When the yield point is reached, the input from the load cell stops increasing, or it increases at a much lower rate, while the potentiometer input continues to rise. This upsets the null balance, and an output signal is given, which can be interpreted as percentage of strain beyond the yield point. Table restretch units are small short-stroke hydraulic cylinders and clamps that can be bolted to the rotary table to give a final stretch set to workpieces that need to be stretched from both ends or restretched after heat treatment. The capacity of a table restretch unit is usually equal to that of the main tensioning gripper.

## Stretch Draw Forming

Stretch draw forming is done with either a form block or a mating die.

**The Form-Block Method.** Bars and structural shapes, although usually radial draw formed, can be stretch draw formed by the form-block method. Also known as drape forming, the form-block method uses either a fixed or a moving form block. A fixed form block is attached to the machine base. Each end of the blank is held by a gripper attached to a hydraulic cylinder. The grippers move to stretch the blank over the form block. Alternatively, the moving

**Fig. 4** Stretch-forming machine with rotary table and sliding center leaf

**Fig. 5** Use of a vertical adapter on the tension unit to accommodate work with bends in two or more planes

form block is attached to a hydraulic piston. A blank is held by grippers while tension is applied to it, and the form block then moves to form the part, as shown in Fig. 1(a).

**The mating-die method** uses a two-piece die mounted in a single-action hydraulic press (Fig. 7). This method combines the advantages of stretch forming and conventional press forming. The stretch forming sets the contours of moderately formed workpieces, and the press forming gives definition to sharply formed contours, such as beads or feature lines on automobile body parts.

Grippers preform the blank over the lower die to the curvature of the part (Fig. 7a). There is very little metal flow; the stretching action and the die form the general outline of the part. The upper die then descends to produce the details and to set the contours (Fig. 7b).

Automatic material-handling equipment can be adapted to the machine for production runs. Production rates are comparable to those obtainable for drawing in conventional single- and double-action presses. Stretch draw press

tooling for large parts, such as automobile roof panels, weighs only one-third that for a conventional double-action press, as indicated in Table 1.

Exposed parts, such as automobile outer body panels, frequently have a maximum surface roughness specification of  $1.1 \mu\text{m}$  (45  $\mu\text{in.}$ ), and stretcher strain marks and other defects, which are still noticeable after painting, must be prevented. One method of avoiding strain marks is the use of segmented or curved grippers, which equalize the amount of stretching. The following example describes the production of a rear-deck lid by stretch draw forming with a mating die.

**Example 1: Stretch Draw Forming of an Automobile Rear-Deck Lid.** Automobile rear-deck lids were produced in a stretch draw press using mating dies, as shown in Fig. 7. The blanks were commercial-quality cold-rolled 1008 steel 0.91 mm (0.036 in.) thick, 1450 mm (57 in.) wide, and 1600 mm (63 in.) long. Residual mill oil was the only lubricant. The production rate was 360 pieces per hour, and annual production was 400,000 deck lids.

Tension was applied to the sheet by the grippers as they moved apart. (Generally, hydraulic cylinders are used to apply the force in this operation.) The tensioned sheet (still held by the grippers) was then lowered to stretch over the lower die. Finally, the upper die was lowered, pressing the sheet into both dies to form the lid.

The cycle time was 7 s. The finished parts showed uniformly good quality without wrinkles or buckles. Approximately 0.9 kg (2 lb) more sheet steel would have been needed to produce this part in a conventional double-action press.

**Lancing.** If stretch drawing is used to form severe contours, the stretch limits of the metal may be exceeded in the zones of deep forming, resulting in fracture of the metal. This can be avoided by lancing the metal in areas to be discarded later so that the metal can flow in the severely formed zones. Single-operation production of a truck-cab roof having a combination of gradual curves and sharp contours is described in the following example.

**Example 2: Stretch Draw Forming of a Truck-Cab Roof with Reinforcing Beads.** By using stretch draw forming with mating dies, the truck-cab roof panel shown in Fig. 8 was produced in one operation. Panels were formed from cold-rolled drawing-quality aluminum-killed 1008 steel. The blanks were 1520 by 813 by 0.89 mm (60 by 32 by 0.035 in.).

With automatic material-handling equipment to load and unload the machine, the production rate was 100 to 150 pieces per hour. Annual production was 25,000 pieces.

The forming dies were of cast iron, with flame-hardened surfaces where severe forming occurred. Radii on the roof beads were 1.0 mm (0.040 in.).

**Table 1 Comparison of conventional and stretch presses**

Press	Capacity							
	Punch		Gripper (blankholder)		Tooling weight		Press height	
	kN	tonf	kN	tonf	kg	tons	mm	in.
Conventional	8000	900	5300	600	20,000	22	7320	288
Stretch	2200	250	760	85	6300	7	5100	200

**Fig. 6** Components and signal-flow diagram of an automatic tension-control system used in stretch forming

**Fig. 7** Production of an automobile rear-deck lid in a stretch draw forming press. (a) Sheet metal blank is tensioned by grippers moving apart. Grippers move down, stretching the workpiece over the lower die. (b) Upper die descends onto the workpiece, pressing the metal into both dies to form the part. (c) After forming, the press opens, and the part is released from the grippers.

## Stretch Wrapping

In stretch wrapping, just enough tension is applied to one end of a workpiece to exceed the yield strength of the material, while the form block revolves into the workpiece with the

turning of the table, as shown in Fig. 1(c). The other end of the workpiece is held in a table gripper or clamped to the end of the form block. The hydraulic cylinder applying tension to the workpiece is free to swivel so that the tension is always tangential to the last point of contact. Thus, the work metal wraps in tension around the form block without the scuffing or friction that occurs with other forming methods. The result is an accurately formed piece with little springback; therefore, form blocks can be made to accurate size.

Because there is no scuffing, form blocks can be made of soft metal, wood, or plastic, although common die materials such as cast iron are often used. Form blocks made of hardwood, masonite, and epoxy have also been used. The contour of the form block can vary throughout the bend, and the workpiece will follow it accurately if there are no concave surfaces on the form block.

Form blocks for the stretch wrapping of rolled and extruded sections are machined to the shape of the section as well as the contour of the finished part. Thus, the shaped form block supports the section during forming. Additional support is sometimes needed for open or hollow sections. A segmented filler, a filler made of low-melting alloy, or a strip of easy-to-form metal can provide this support. Return bends can be made by using additional form blocks on sliding leaves of the turntable and by reversing the table direction to produce the part, as shown in Fig. 9.

**Machines** for stretch wrapping consist basically of a variable-speed power-driven rotary table and a double-action pressure-controlled hydraulic cylinder. The form block is bolted to the table. Grippers are connected to the hydraulic cylinder so that tension can be applied to the workpiece, as in Fig. 1(c). The fabrication of a typical part by stretch wrapping is described in the following example.

**Example 3: Forming of an Aircraft Leading-Edge Wing Panel by Stretch Wrapping.** A corrugated leading-edge wing panel of aluminum alloy 6061-O was stretch wrapped in a stretch-forming machine with a vertical-axis turntable. The sheet, with corrugations in the direction of airflow, was gripped at each end with grippers shaped to fit the corrugations. The tension applied was slightly above the yield strength of the work metal. The form block, bolted to the

turntable, rotated slowly into the workpiece, causing it to form smoothly into the shape of the wing without flattening the corrugations. While the form block was moving in the sheet, the hydraulically restrained gripper maintained tension slightly above the yield point. The form block was made to the required final shape without allowance for springback because only a small amount of springback occurred.

## Compression Forming

In compression forming, the workpiece is pressed against the rotating form block instead of being wrapped around it. The process is typically used for maintaining or controlling workpiece cross-sectional dimensions throughout the contour, for bending to radii small enough to exceed the elongation limits of the metal if formed by stretch wrapping, and for bending sections too heavy for the capacity of the available stretch wrap machinery.

Compression forming can generally be done in the same machine as stretch wrapping, but the hydraulic cylinder is used to apply pressure instead of tension to the workpiece. The cylinder is locked in place to keep it from swiveling, and the ram head is furnished with a roller or a shoe to press the workpiece against the form block. A clamp or table gripper holds the end of the workpiece against the form block, and as the table rotates, the shoe or roller on the hydraulic cylinder presses the workpiece into the contour of the block, as shown in Fig. 1(d).

Compression forming can often make bends to a smaller radius than stretch wrapping in a part

that has a deep cross section. If the same bend were produced by stretch wrapping, fracturing or overstressing of the outer fibers would result. The total load needed to form large-section pieces, such as cross rails and bumpers, can be as little as 2% of that needed to form them in a punch press. The total energy applied to the workpiece would of course be the same (neglecting efficiency); the smaller compression-forming force is applied for a longer period of time. The wiping shoe or roller can hold the cross-sectional size and shape to close tolerance throughout the contour. Parts that are too heavy in cross section for stretch wrapping can often be compression formed.

Blanks for stretch forming are usually made longer than the finished part so that the surface damaged by the gripper jaws can be trimmed off. However, end details, locating surfaces, and other considerations occasionally necessitate the use of a blank cut to the length of the finished part, and dimensional tolerances still must be met, as in the following example.

**Example 4: Use of an Adjustable Form Block to Compression Form a Developed Blank.** Because both ends of the piece shown in Fig. 10 had previously produced details, the part could not be trimmed after forming. Instead of a table gripper or clamp, the blank was fastened to the form block by bolts through two 21 mm ( $13/16$  in.) diameter holes pierced in one end. The blank was cut slightly shorter than the required length because the length increased from 3.602 to 3.613 m (141.81 to 142.25 in.) during forming.

The 1020 steel structural shape that was being compression formed had considerable springback, which varied with each heat of steel.

**Fig. 8** Beaded truck-cab roof that was stretch draw formed with mating dies. Dimensions given in inches

**Fig. 9** Stretch wrapping of a part around three form blocks to make two reverse bends

To obtain uniform results, the form block was made adjustable. As shown in Fig. 10, the wear plate, made of 19 mm ( $\frac{3}{4}$  in.) thick by 203 mm (8 in.) wide high-carbon steel, was backed up with jackscrews that could be adjusted to change the effective radius. One end of the wear plate was fastened to the base plate, and the other end was free to move in and out of any position, supported by the jackscrews. When a new lot of steel was delivered, an experimental piece was run to determine springback, and the jackscrews were adjusted accordingly.

The work material was a hot-rolled channel 152 mm (6 in.) wide, weighing 15.6 kg/m (10.5 lb/ft), approximating a 1020 steel in composition. The piece was compression formed on a radial draw former into a half circle with a 1145 mm (45 in.) radius. The two holes in the end of the piece were used to connect this section with a fishplate on one end of a mating piece to form an assembled ring. The sequence of operations was as follows:

- Saw ends with a 3° bevel to developed length (3.602 m, or 141.81 in.)
- Deburr
- Pierce two 21 mm ( $\frac{13}{16}$  in.) diameter holes
- Form both ends to 1145 mm (45 in.) radius for 152 to 203 mm (6 to 8 in.) of length on a press brake
- Bolt the workpiece to the form block by the two pierced holes. Compression form to 1145 mm (45 in.) radius
- Galvanize after forming
- Flatten as necessary (galvanizing sometimes causes warpage)

A straight mineral oil was used as the lubricant. The overall tolerance on the formed curve was 1.5 mm (0.060 in.) total indicator reading.

**Fig. 10** Steel channel that was compression formed without trim allowance using an adjustable form block. Dimensions given in inches

Production time was 3 min per piece with two operators, and setup time was 1 h. The production-lot size was 250 pieces.

**Two-Plane Curvature.** When a part must have curvature in two or more planes, a vertical adapter, either hydraulic powered or screw actuated, is used to permit the ram gripper to move up and down as the work requires. Thus, the work material can be fed into a spiral or other form involving rising and falling curvatures. In the following example, a vertical adapter with a wiper shoe was used to form a low-angle helix that was later welded into a ring.

**Example 5: Producing a Ring from a Helix to Counteract Springback.** Because springback in the forming of a titanium alloy engine ring made it difficult to weld the workpiece into a true circle after forming, the stock was compression formed into a low-angle helix by using a vertical adapter with a wiper shoe. The form block was smaller in diameter than the finished ring, and when the workpiece was removed from the form block, springback was just sufficient to permit welding into a true ring. The setup used for forming the ring is shown in Fig. 11.

## Radial Draw Forming

Radial draw forming is a combination of stretch wrapping and compression forming, as shown in Fig. 1(e). As in stretch wrapping, one end of the workpiece is gripped by stationary jaws attached to the rotary table. The other end is gripped by jaws on the hydraulic cylinder. The cylinder exerts tension on the workpiece as the form block on the rotary table revolves into it. A second hydraulic unit, fitted with a wiper shoe or roller, presses the workpiece into the contour of the form block at the point of tangency. The hydraulic unit applying the compression force can be moved as necessary to keep the wiper shoe in contact with the workpiece. On large machines, an operator sometimes rides a platform on the second unit to observe the point of contact.

Joggles in rolled or extruded sections can be formed after the part has been radial draw formed, without removing the part from the form

**Fig. 11** Use of a vertical wiper-shoe adapter to form a helical shape. After forming, springback of the titanium alloy used brought the formed piece into a circular shape, which could be welded into a ring.

block. When contour forming is completed, the part is held in tension while the compression unit is repositioned, and the joggle is formed by the wiper shoe. The wiper shoe is sometimes used to apply pressure to a loose joggle block (Fig. 12) if the wiper shoe will not provide the correct shape for the joggle. In either case, the shape of the joggle is also machined into the form block. The vertical adapter shown in Fig. 5 can be used in the radial draw forming of bends in two or more vertical planes.

Architectural sections, extruded shapes, and other sections sometimes have to twist on themselves if they are contour formed through any plane other than the plane of symmetry. In radial draw forming, this can be done by permitting the workpiece to rotate axially as the part follows the twisting contour of the form block. Rotation is obtained by slightly loosening the lock ring on the body of the gripper head, allowing the head to rotate about its own centerline. The following example illustrates the forming of an angle section by this method.

**Example 6: Twisting of an Angle Section during Contour Forming.** An L-shaped section for the gunwale of an air-sea rescue craft (Fig. 13) had to be twisted as it was radial draw formed. It was made of aluminum alloy 2024-T4. Forming had to be done in several planes. The locking ring of the gripper was loosened, permitting the head to rotate as the part was formed. The usual production-lot size was 500 pieces. Parts were formed at the rate of 10 per hour.

**Fig. 12** Forming a joggle with a loose block and a wiper shoe after radial draw forming

**Fig. 13** Gunwale section that was produced from an L-section by a combination of twisting, stretching, and forming in several planes

## Stretch-Forming Machines for Large Parts

Drape-forming machines are designed to be used on relatively small lengths and widths. The stretching and bending of greater lengths and widths require the increased capacity of stretch-forming machines. Stretch-forming machines bend the workpiece around the die to elongate the material fibers while simultaneously preventing wrinkles and minimizing springback.

These machines are available in two basic types:

- Moving jaws only, to stretch the blanks around a stationary form block
- Moving jaws combined with a moving-die (form-block) table

Transverse or longitudinal models and combination transverse-longitudinal models are available. Selection of the appropriate machine (jaw width, distance between jaws, and force capacity are key specifications) is determined by the configuration and dimensions of the workpiece.

**Transverse Machines.** The jaws of transverse machines, on which the workpieces are stretched and bent transversely, must be as long as the workpiece to provide substantial area for gripping. The transverse machine shown in Fig. 14 has a movable die table that can be tilted  $15^\circ$  above or below the horizontal. The jaws can be swiveled  $30^\circ$  in a horizontal plane and  $90^\circ$  in a vertical plane so that the direction of stretching can be aligned with the contour of the die. Rated at 6700 kN (750 tonf), the machine has a 2080 mm (82 in.) stroke, a 25 to 3660 mm (1 to

144 in.) jaw distance, and a 25 to 457 mm/min (1 to 18 in./min) forming speed. This equipment is primarily used for forming large sheets, such as fuselage skins and the leading edges of airplane wings. Large, cumbersome extrusions, such as wing spars, can be formed by changing or adapting the jaws.

**Longitudinal Machines.** The longitudinal stretch-forming machine shown in Fig. 15 can be swiveled  $90^\circ$  but cannot be raised or lowered. The 2540 mm (100 in.) wide, hydraulically powered, leadscrew-actuated jaws are made in sections for curvature to various radii. These jaws can be swiveled both horizontally and vertically. Each individual jaw develops a 6700 kN (750 tonf) tensile force, and the jaws in tandem are capable of forming 12 by 2.4 m (40 by 8 ft) sheet metal skins. The addition of adapter jaws bolted to the standard jaws allows the machine to form long extruded frame members weighing up to 450 kg (1000 lb).

## Dies and Tooling

Traditional dies for stretch forming are made of zinc alloys, steel, plastics, or wood. Non-traditional tools include a recently developed reconfigurable tool system for stretch-forming applications.

**Reconfigurable Stretch-Forming Tool.** A new stretch-forming tool system for producing large panels with little curvature was recently developed and successfully demonstrated on aircraft parts. The system includes a universal tool that could be reconfigured to produce different part shapes. The working surface of the tool consists of a large number of steel pins with

hemispherical tips. The position of each pin can be changed to accommodate the required shape of the panel. The shape of the die is the envelope of the pin tips, and pin settings are computer controlled to produce the required part shape. A flexible polymer layer is inserted between the tool and the sheet metal during stretch forming to suppress dimpling. The tool can be reconfigured to produce different contoured shapes, such as aircraft wings and fuselage panels.

Figure 16 shows schematic views of the tool design. The overall size of the prototype tool is 1.83 by 2.44 by 1.07 m (6 by 8 by 3.5 ft), and the working volume of the tool surface is 1.22 by 1.83 by 0.31 m (4 by 6 by 1 ft). Individual pins are grouped into modules, and the entire tool is composed of 336 identical modules. Each module can be removed from the tool without disturbing the other modules. A computer with graphical user interface permits configuration of pins to the desired tool shape. Limitations of this technology include minimum radius of curvature and restrictions on the shapes of parts that can be produced. This technology is attractive for low-volume production. It also reduces cost and time by eliminating the need to fabricate as well as store traditional tools and enables transition to a factory with fewer tools.

## Accuracy

High-strength alloys, stainless steel, and titanium can be stretch formed to overall tolerances of  $\pm 0.25$  mm ( $\pm 0.010$  in.) on workpieces bent to approximately a 178 mm (7 in.) radius. With springback allowance, bends can be controlled to  $\pm 1/2^\circ$ . Cross-sectional dimensions have been

**Fig. 14** Transverse stretch-forming machine having both movable and tiltable die table and swiveling, movable jaws

Fig. 15 Longitudinal stretch-forming machine with leadscrew-actuated jaws that can be curved and swiveled both horizontally and vertically

Fig. 16 Schematic views of the modular design of the full-scale reconfigurable stretch-forming tool

held to  $\pm 0.05$  mm ( $\pm 0.002$  in.) by close control of raw material, as in the following example.

**Example 7: Maintaining Close Tolerances on Grooves While Forming a Guide-Vane Shroud.** Because a cover strip had to slide easily, but without play, into the grooves of a stainless steel guide-vane shroud after the vanes were assembled, the width of the grooves had to be held within 0.10 mm (0.004 in.), as shown in

Fig. 17. Strip was selected that had thickness variation within  $\pm 0.013$  mm ( $\pm 0.0005$  in.) because of the close groove tolerances that had to be met. The two U-bends forming the grooves were made in a press brake, and the guide slots were pierced in another operation. The shrouds were then contoured to a 190 mm ( $7\frac{1}{2}$  in.) radius by stretch forming. The width of the work strip and the width of the grooves were

Fig. 17 Guide-vane shroud that was stretch formed without noticeable distortion to the 0.51/0.61 mm (0.020/0.024 in.) groove dimension. Dimensions given in inches

held within the specified tolerances without using filler for support.

The shrouds were produced at a rate of 10 per hour. A typical production run was between 200 and 1000 pieces.

**Tolerance Specifications.** As shown in the preceding example, it may be necessary to control stock to a small thickness variation if close tolerances on the workpiece must be met. Ordinarily, it is good practice to allow approximately 25% of the finished-part tolerance as the stock thickness tolerance or the tolerance on any preformed dimension that could affect the accuracy of the stretch-formed dimension. In Example 7, the smallest tolerance was  $\pm 0.05$  mm ( $\pm 0.002$  in.), and the stock thickness variation was controlled to  $\pm 0.013$  mm ( $\pm 0.0005$  in.) (25% of workpiece tolerance).

Titanium is stretch formed both hot and cold (see the article "Forming of Titanium and Titanium Alloys" in this Volume). In cold stretch

forming, shrinkage at right angles to the stretch is ordinarily controlled to  $\pm 0.79$  mm ( $\pm 1/32$  in.) on bends with 229 mm (9 in.) radii. Angular variation on stretch bends in all materials is held to  $\pm 1/2^\circ$ .

In one plant, large rectangular tubing of copper alloy is stretch formed with a filler or with a flexible mandrel similar to those described in the article "Bending and Forming of Tubing" in this Volume. Tubes as large as 102 to 203 mm (4 to 8 in.) square and up to 4.9 m (16 ft) long with 3.2 to 9.5 mm ( $1/8$  to  $3/8$  in.) walls can be formed. When mandrels are not used, distortion appears as concavity in the face away from the form block and some tapering toward the concave face, as shown in Fig. 18. These tubes are stretch formed to large radii with a  $\pm 0.80$  mm ( $\pm 1/32$  in.) tolerance on the radius of the bend.

In the bending of large tubing, the bend is usually so shallow that the elastic limit of the metal is not reached without gross overbending, unless stretch-forming methods are used. As with conventional methods, overbending leads to unpredictable results. Tolerances on shallow bends can seem deceptively large. To hold a 3.0 m (10 ft) radius within  $\pm 0.80$  mm ( $\pm 1/32$  in.) in a  $10^\circ$  arc means holding an overall tolerance of more than  $\pm 0.13$  mm ( $\pm 0.005$  in.).

## Surface Finish

Little can be done in stretch forming to improve surface finish, because tool contact with the surface is incidental. However, some practices can be implemented to help preserve the original finish:

- Avoid overstretching. With most materials, 2 to 4% stretch is sufficient to achieve the results desired in stretch forming. The overstretching of some metals, such as aluminum, simply because they are ductile is a common mistake. This leads to the appearance of stretcher strains or other surface relief effects.
- Plastic wiper shoes can be used in the compression forming or radial draw forming of aluminum alloys to avoid marring the surface. With stainless steel workpieces, well-finished plastic wiper shoes are used with drawing compounds similar to those used for severe deep drawing.

Fig. 18 Typical distortion of square copper alloy tubes in stretch forming. Dimensions given in inches

An extrafine finish is necessary in order to protect the surfaces of aluminum alloys directly in contact with the form block. Special practices used to preserve the finish include cleaning to eliminate abrasive dust particles, the use of polyvinyl chloride instead of a lubricant, and the use of special carrier sheets for protection of the surface during forming.

## Stretch Forming Compared with Conventional Drawing

**Example 8: Stretch Draw Forming versus Conventional Drawing.** This example compares stretch draw forming with drawing for a part manufactured by an automotive supplier. Stretch forming was competitive for quarter-pillar lock panels produced from 0.89 mm (0.035 in.) thick commercial-quality 1008 steel by conventional drawing. In drawing, an 8900 kN (1000 tonf) double-action press with conventional draw dies produced 525 pairs of panels per hour. In stretch draw forming, a 7200 kN (800 tonf) 2.74 by 1.52 m (108 by 60 in.), straight-side, single-action mechanical press with 1.22 m (48 in.) long stretch grippers was used. The production rate was the same as that for the conventional press when automatic loading and unloading were used, and the production cost was less. The process was changed to stretch draw forming.

In high-production forming, the principal disadvantage of stretch forming is the slowness of the hydraulic units used on the grippers, unless pumps of excessively high capacity are used. Mechanical units are available that have rapid response.

## Operating Parameters

Size and configuration of the workpiece, material composition, type of forming operation used, machine and tooling used, and production requirements are among the variables that influence stretch forming. Operating parameters, such as force requirements, and the lubricant used must be determined prior to forming.

**Force Requirements.** The application of excessive tension in stretch forming can cause breakage of the workpiece. On the other hand, too little tension can result in poor contouring, wrinkling, or springback of the formed part. The force capacity of the machine required for stretch forming a part can be calculated by:

$$F = \left( \frac{Y_s + \text{UTS}}{2} \right) A \quad (\text{Eq 1})$$

where  $F$  is the stretch-forming force (in pounds of force),  $Y_s$  is the yield strength of the material (in pounds per square inch), UTS is the ultimate tensile strength of the material (in pounds per square inch), and  $A$  is the cross-sectional area of

the workpiece (in square inches). To convert from English units (pounds of force) to metric units (newtons), the force in pounds is multiplied by 4.448.

The estimate of the force required for stretch forming obtained with Eq 1 is generally an average. To compensate for work hardening, friction, more complex contours, and other variables, the force obtained mathematically should be increased by an additional 25% for some applications.

**Lubrication.** In most stretch forming, little or no lubrication is needed, because the movement between the work metal and the form block is minimal. On sheet steel, residual mill oil is usually sufficient, although some operators spray the stock with light lubricating oil as it enters the forming area. Lubricants are sometimes intentionally avoided because they attract and retain dust particles that could mar the workpiece surface.

In the compression forming of copper alloys, low-carbon steel, and stainless steel, in which a shoe rubs hard against the part or there is considerable movement against the form block, white lead thinned with SAE 30 engine oil can be brushed on the workpiece before forming. In some shops, molybdenum disulfide is similarly used on low-carbon steel. Both lubricants resist heat and pressure and reduce friction. Polyvinyl chloride sheet can be used in place of a lubricant (and to embed dust particles) in the forming of microwave reflectors.

# Superplastic Sheet Forming

A.K. Ghosh, University of Michigan  
C.H. Hamilton

SUPERPLASTICITY is a term used to indicate the exceptional ductility that certain metals can exhibit when deformed under proper conditions. The term is most often related to the ductile tensile behavior of the material; however, superplastic deformation has the characteristic of easy deformation under low pressures, and compression deformation characteristics are also described as superplastic. The tensile ductility of superplastic metals typically ranges from 200 to 1000% elongation, but ductilities in excess of 5000% have been reported (Ref 1). Elongations of this magnitude are 1 to 2 orders greater than those observed for conventional metals and alloys, and they are more characteristic of plastics than metals.

Because the capabilities and limitations of sheet metal fabrication are most often determined by the tensile ductility limits, it is clear that there are significant advantages potentially available for forming such materials, provided the high-ductility characteristics observed in the tensile test can be used in production forming processes. This is of course being done, and the number of applications of parts formed by these methods is increasing each year. This article discusses many of the processes and related considerations involved in the forming of superplastic sheet metal parts.

## Requirements for Superplasticity

Before discussing the details of the superplastic forming (SPF) processes, it is necessary to review the more important aspects of superplastic material behavior, because some of the specific forming parameters are determined by this behavior. There are several different types of superplasticity in terms of the microstructural mechanisms and deformation conditions, including the following (Ref 2, 3):

- Micrograin superplasticity
- Transformation superplasticity
- Internal stress superplasticity

At this time, only the micrograin superplasticity is of importance in the fabrication of parts, and the discussion is limited to this type.

For micrograin superplasticity, the high ductilities are observed only under certain conditions, and the basic requirements for this type of superplasticity are:

- Very fine grain size material (of the order of 10  $\mu\text{m}$ , or 400  $\mu\text{in.}$ , or finer)
- Relatively high temperature (greater than approximately one-half the absolute melting point), although reduced forming temperature by using finer-grain materials is a goal at this time
- A controlled strain rate, usually 0.0001 to 0.1  $\text{s}^{-1}$

Only a limited number of commercial alloys are superplastic, and these materials are formed using methods and conditions that are different from those used for conventional metals. However, increasingly more and more alloys have been grain-refined to induce superplasticity in them.

**Characteristics of Superplastic Metals.** For a superplastic metal that is tensile tested under proper conditions of temperature, the observed ductility is seen to vary substantially with strain rate, as shown in Fig. 1 for a zinc-aluminum eutectoid alloy (Ref 4). As shown, there is a maximum in ductility at a specific strain rate, with significant losses in ductility as the strain rate is increased or decreased relative to this maximum. It is well known that the primary factor related to this behavior is the rate of change of flow stress with strain rate, usually measured and reported as  $m$ , the strain-rate sensitivity exponent:

$$m = \frac{\partial \ln \sigma}{\partial \ln \dot{\epsilon}} \quad (\text{Eq 1})$$

where  $\sigma$  is the flow stress, and  $\dot{\epsilon}$  is the strain rate.

The aforementioned characteristics of a superplastic alloy indicate that unusual forming capability should be possible with superplastic

**Fig. 1** Tensile fracture strain versus initial strain rate for a Zn-22Al alloy having a grain size of 2.5  $\mu\text{m}$  (100  $\mu\text{in.}$ ) tested at temperatures ranging from 423 to 503 K

alloys but that control of the forming process parameters is important to obtain the full potential of this class of material. Such process controls are more demanding than corresponding requirements for conventional forming processes, and the superplastic forming of sheet metals is a technology that is different from the conventional processes. However, superplastic forming offers advantages over other fabrication methods for a number of applications as a result of its unique capability of fabricating complicated components in a single step.

**Superplastic Alloys.** Because of the stable grain size requirement for a superplastic metal, not all commercially available alloys are superplastic. Many materials have been produced with laboratory or pilot-plant processing, but very few of these have been produced commercially (Ref 3), although greater interest is now seen for their commercial production. As SPF technology develops, alloys are not only being used for aerospace and architectural use but also for automotive application in production volume cars.

A summary of several superplastic alloys is presented in Table 1, along with some of their characteristics. Particularly noteworthy are Ti-6Al-4V, aluminum alloy 7475, and the Supral alloys, which are quite superplastic and are commercially available. Among aluminum alloys, and particularly aluminum-magnesium alloys, alloy 5083 is a favored alloy for superplastic-formed parts in the automotive industry. Optimal superplastic conditions have been determined for fine-grained 5083 aluminum (Ref

5–8); however, the automotive industry generally practices nonoptimal conditions (lower temperature and faster strain rate), to be competitive with mass-production technologies. Low-temperature superplasticity or warm forming of sheet is gaining a great deal of attention for its potential for rapid forming at slightly elevated temperatures. Grain refinement to ultrafine grain sizes ( $<2$  to  $3\text{ }\mu\text{m}$ , or  $80$  to  $120\text{ }\mu\text{in.}$ ) is becoming more commonplace to permit high ductility. This is currently of interest in relation to magnesium alloys, with potential for lightweight application in the auto industry and space business. Table 2 presents a compilation of superplastic tensile properties of various magnesium alloys, showing that grain refinement is instrumental in making these and other hexagonal close-packed metals highly favorable at low forming temperatures. Titanium alloys are generally superplastic as conventionally produced, although there has not been a need to develop alloy modifications or special mill-processing to make them superplastic. However, this has not been the case with the aluminum alloys, and either special processing (Ref 26) or alloy development (Ref 27) has been necessary to produce superplastic materials. Presently (2006), ultrafine-grain titanium is being produced to reduce the forming temperature of titanium alloys. The Zn-22Al alloy has been the focus of substantial research, because it can be readily processed into the superplastic condition; this alloy has also been made available commercially, but interest in this alloy is much reduced.

Additional information on superplastic alloys is available in the articles “Forming of Aluminum Alloys” and “Forming of Titanium and Titanium Alloys” in this Volume. Superplastic ferrous alloys are discussed in the section “Superplasticity in Iron-Base Alloys” in this article.

## Characterization of Superplastic Alloys

The characteristic flow properties of a superplastic metal are exemplified in Fig. 2 for a Ti-6Al-4V alloy tested at  $927\text{ }^{\circ}\text{C}$  ( $1701\text{ }^{\circ}\text{F}$ ). The very strong dependence of  $m$  on strain rate at various grain sizes (Fig. 3) is typical of superplastic metals, and there is a good correlation between the  $m$ -value and superplastic ductility. This relationship is demonstrated most clearly in Ref 28 in a graph of data for a large number of alloys in which the  $m$ -value is graphed as a function of elongation. Although the total elongation can also be affected by fracture, the strain-rate sensitivity is a first-order effect. The influence of  $m$  on the ductility is understood through mechanics of diffuse neck growth, which slows with increasing value of  $m$ , a stabilizing effect of the strain-rate sensitivity of flow stress (Ref 29–31). The strong effect temperature has on superplastic deformation is demonstrated most clearly in Ref 32, in which the ductility of a titanium alloy is graphed as a function of temperature. The elongation of the titanium alloy rises and falls rapidly over a relatively short temperature range, and outside the limits of this temperature span, the ductility is modest in the range of conventional material behavior.

The characterization of superplastic behavior includes the characterization of plastic flow, internal cavitation, and fracture behavior. The processing variables needed for an overall characterization of superplastic behavior are introduced in this section. The parameter that is commonly selected as a measure of superplastic formability is the tensile elongation at the optimal superplastic temperature and strain rate. Because this is a highly strain-rate-sensitive property and because real components can experience significant variations in strain rate during forming, tensile elongation is measured as a function of strain rate. Although this is somewhat time-consuming, an alternative is to determine the strain-rate sensitivity of the flow stress,  $m$ , which has been shown to correlate well with tensile elongation for different classes of materials (Ref 28, 29). Measurements of flow stress and strain-rate sensitivity of flow stress can be conducted in a single test and can be used to determine the optimal strain rate for superplastic forming (where  $m$  is a maximum). Although strain-rate sensitivity is the dominant parameter in superplastic forming in a great many superplastic alloys, a significant amount of hardening can occur as a function of strain, even at a constant strain rate (Ref 30, 31). This type of

strain hardening is related primarily to the grain growth that occurs during superplastic forming. At higher strain rates, strain hardening is associated with dislocation cell formation in the classical manner, and grain growth is not observed.

Forming temperature is just as important a variable in superplastic forming as the strain rate. Temperature variation in a forming die is a primary source of localized thinning. Characterization of material behavior must include not only determination of the optimal superplastic temperature but also the sensitivity of flow stress and elongation to temperature. A large temperature sensitivity of flow stress is not desirable, because local hot spots will lead to severe strain localization. When strain localization and necking are the dominant modes of failure, it has been

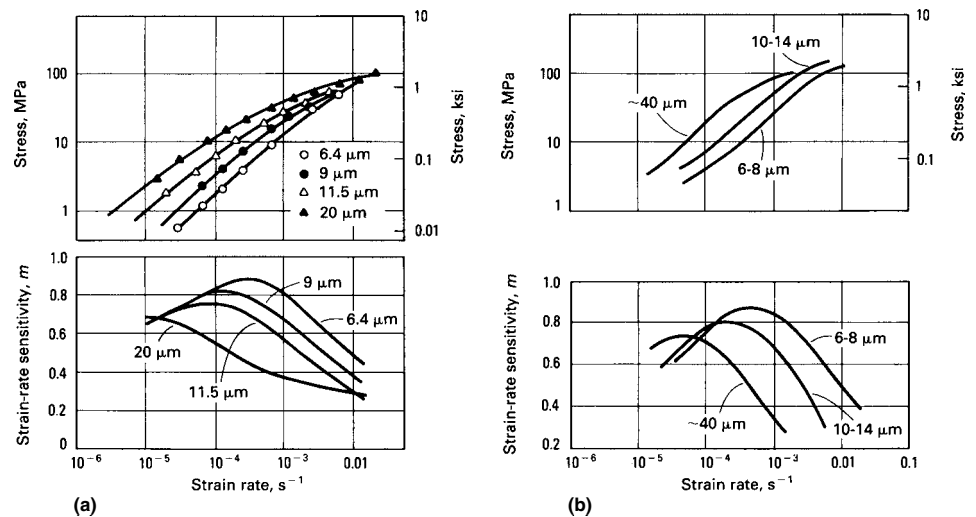

shown that tensile elongation is related to the  $m$ -value in a predictable manner (Ref 32). However, when fracture intervenes, the  $m$ -value does not provide sufficient quantitative characterization, although within the same alloy system it still provides a qualitative comparison. Fracture is therefore an important consideration in most superplastic materials of engineering application and is preceded by internal cavitation. An exception is materials with anomalously high diffusivity (for example, Ti-6Al-4V alloys), which do not show any evidence of internal

cavitation or fracture under typical superplastic forming conditions. Superplastic materials that exhibit cavitation at inclusions, triple points, and second-phase particles generally fail by the interlinking of growing cavities.

**Stress-strain-rate behavior** is usually characterized by a step strain-rate test, in which strain rate is increased in successive steps and an attempt is made to measure the corresponding steady (or saturated) flow stress. A constant flow stress indicates a negative loading rate, which occurs at a point somewhat beyond the load

**Fig. 2** Schematic plot of load versus time for the tensile deformation of a superplastic Ti-6Al-4V alloy at 927 °C (1701 °F) and at progressively increasing crosshead velocities (step strain-rate test)

**Fig. 3** Stress-strain-rate plots and the corresponding strain-rate sensitivity plots from step strain-rate tests for (a) Ti-6Al-4V at 927 °C (1701 °F) and (b) 7475 aluminum alloy at 516 °C (961 °F), which are both at superplastic temperature

maximum. However, even if the load maximum is used as a criterion for calculating these stresses, it can be shown that the error is negligible, except when considerable strain hardening occurs. In these cases, characterization of strain hardening is carried out separately. For these cases, the knee of the stress-strain curve, past the "yield" point, is the most reasonable representation of isostructural flow stress. Various arguments have been put forward for the proper selection of flow stress from transient loading response (Ref 33–35). However, because of the changing plastic-strain rate during this test, selection of data at the elastic limit from the rapidly rising portion of the load curve is inappropriate.

Figure 2 shows a schematic load versus time plot during a step strain-rate test of a typical superplastic alloy. The interesting features are:

- At the low crosshead speeds, the load does not reach a maximum but continues to show a gradual rise.
- At some intermediate speed, load reaches a constant plateau.
- At higher speeds, it peaks and begins to show a sharp drop.

The load increase at the low strain rates, in spite of a decrease in applied strain rate, indicates hardening of the material with imposed strain. A part of this hardening is due to a rise in plastic-strain rate, which occurs gradually when crosshead speed is low. However, the extent of hardening observed is considerable and does not saturate even after significant plastic strain. This type of hardening has been observed in many superplastic materials, such as aluminum-copper eutectic, aluminum-magnesium, and Al-Zn-Cu-Mg alloys, and is generally attributed to grain growth occurring during deformation (Ref 36, 37).

The criticism against the use of strain-rate jump tests and the selection of maximum load points for obtaining stress values is that the strain automatically becomes a variable along the  $\sigma$ - $\dot{\epsilon}$  curve. This could be avoided if load relaxation test results were used to derive  $\sigma$ - $\dot{\epsilon}$  curves. However, more complex transient effects are associated with load relaxation tests, and the results may not be meaningful for a forming application in which strain rate generally increases with accompanying strain. The step strain-rate test is therefore believed to be a logical test method for use in superplastic forming applications, provided the data are obtained with very little strain accumulation.

The  $\sigma$ - $\dot{\epsilon}$  data for Ti-6Al-4V alloy and 7475 aluminum alloy deformed in the superplastic temperature range are presented in Fig. 3 for a variety of grain sizes. The total accumulated strain is generally less than 0.25 in these tests. At lower strain rates ( $<5 \times 10^{-4} \text{ s}^{-1}$ ), strain hardening does not permit the establishment of a load maximum. To characterize flow stress free from grain-growth hardening effects, stresses must be selected soon after the elastic portion. If the load

rises slowly, the plastic-strain rate,  $\dot{\epsilon}_p$ , can be obtained from:

$$\dot{\epsilon}_p = \dot{\epsilon}_t - \frac{1}{E} \left[ \frac{\dot{P}}{A} + \frac{P}{A} \dot{\epsilon}_t \right] \quad (\text{Eq 2})$$

where  $\dot{\epsilon}_t$  is the applied strain rate,  $E$  is Young's modulus,  $P$  is the load,  $\dot{P}$  is the loading rate, and  $A$  is the instantaneous area.

The second term within the brackets in Eq 2 can generally be neglected, and even the first term can be neglected for most metals where  $\dot{P}/A < 0.015 \text{ MPa s}^{-1}$  ( $0.0022 \text{ ksi s}^{-1}$ ). Therefore, for most purposes,  $\dot{\epsilon}_p = \dot{\epsilon}_t$  is a reasonable assumption as long as the loading rate is low (it need not be zero). The stress versus strain-rate data plotted on the basis of such small strain accumulation serve as the initial behavior of the superplastic material. Deformation produces changes in this behavior, however, and a stress versus strain-rate plot taken after considerable plastic strain exhibits a higher stress level compared with the initial curve (Ref 30).

The proper method for determining  $m$  from step strain-rate test results is to obtain the slope of the curve of best fit through the  $\log \sigma$  versus  $\log \dot{\epsilon}$  data. The determination of  $m$  from two consecutive strain-rate jumps assumes a constant  $m$  over that strain-rate range and introduces an error that is dependent on the size of the range of jump strain rates. Figure 3 shows that grain size has a strong effect on flow stress and  $m$ -value in the superplastic range. Because of the sigmoidal shape of the stress-strain-rate curves,  $m$ -values exhibit a maximum at an intermediate strain-rate, and the  $m$ -peak shifts to higher strain rates with decreasing grain size. In titanium and aluminum alloys under optimal temperature and strain rate, the value of the  $m$ -peak is typically in the range of 0.7 to 0.9 and increases with decreasing grain size. The value of  $m$  also exhibits a maximum as a function of temperature. The effects of grain size and temperature are

closely tied to the diffusional creep contribution during superplastic flow (Ref 38, 39). In the power-law creep regime (at higher strain rates), however, the stress values tend to converge for different grain sizes as the grain size dependence decreases.

**Grain Size Distribution Effects on Stress-Strain Rate.** Grain size has a profound influence on the superplasticity of metals. When the grain size is fine, the flow stress is low, the value of  $m$  is generally high, and the tensile elongation is greater. Characterization of grain size is therefore important in the overall characterization of superplasticity. However, because polycrystalline aggregates, in general, possess a distribution of grain size, it is not very meaningful to assign a fixed grain size to metals. The nature of the distribution has also been shown to influence the stress-strain-rate curve (Ref 40, 41). A few coarse grains in an otherwise fine grain structure can control the strain-rate range over which  $m$  is high and may, in some cases, cause the appearance of a threshold stress. The important effect of grain size distribution in real materials is to produce a broader strain-rate range for high  $m$ , that is, a relatively high  $m$  ( $m > 0.5$ ) over almost three decades in strain rate; this is a transition region between power-law creep and diffusional creep (Fig. 4).

**Stress-Strain Behavior.** Superplastic metals are generally regarded as ideally rate sensitive; that is, no strain hardening occurs during deformation. However, grain-growth-induced strain hardening occurs, and it can be quite significant in some cases (Ref 30, 31, 36, 37). In testing superplastic materials, constant crosshead speed leads to a decreasing strain rate within the specimen gage length, particularly at large tensile strains. An effort to maintain constant strain rate requires that:

- The specimen fillet region be reduced to a minimum to reduce its contribution to the overall extension

Fig. 4 Influence of different grain size distributions on the steady-state stress-strain-rate curves. The solid lines are for essentially singular grain sizes. Distribution in grain size yields a gradual transition in stress-strain-rate curves.

- The crosshead speed be programmed to increase with specimen elongation in order to maintain a constant strain rate (assuming the elongation to arise uniformly out of the gage length)

An on-line computer serves this function by altering the crosshead speed,  $v$ , in the following manner:

$$v = l_0 \dot{\epsilon}_t \exp(\dot{\epsilon}_t) \quad (\text{Eq 3})$$

where  $l_0$  is the initial gage length,  $\dot{\epsilon}_t$  is the applied strain rate, and  $t$  is the time from the start of test. Temperature control during the test also must be accurate (within 2 °C, or 4 °F) in order to avoid

any localized deformation. The crosshead speed control process is a function of strain distribution within the specimen, which is now controlled by using a considerably more sophisticated computer program, as illustrated in Ref 42.

Figure 5 shows the stress-strain curves for titanium and aluminum alloys obtained at various constant strain rates. The extent of hardening is quite large and appears to produce a linear stress-strain behavior. In diffusional creep, one can expect  $\sigma \sim d^2$ ; if grain growth kinetics are such that  $d \propto t^p$ , where  $t$  is time,  $p$  is the exponent, and  $d$  is grain size, then  $\sigma \propto t^{2p}$ . When  $p$  is approximately 0.5, a linear hardening behavior would be expected. If diffusional creep due to

grain-boundary transport is considered,  $\sigma \propto d^3$ , and  $p$  may be as low as 0.33, thus causing the appearance of linear hardening. In reality, the value of the hardening exponent,  $2p$  or  $3p$ , may be somewhat less than unity. A small component of strain-rate-dependent increase of flow stress also influences these experimental results, because strain rate does not remain absolutely constant during the tests. The last portion of the stress-strain curves (shown dashed or with stress drop) is where nonuniformity of deformation within the gage length makes stress measurements incorrect.

The significant strain hardening observed in Fig. 5 is believed to be due to concurrent grain growth, the evidence for which is shown in Fig. 6. In the case of Ti-6Al-4V, the grain growth kinetics appear to some degree to be a function of strain rate as well. It is clear, however, that slower strain rates produce the largest grain sizes, particularly because of the long exposure times, and in all cases, dynamic grain growth is significantly greater than static growth.

Concurrent grain growth effects can also influence the stress-strain rate data measured at the low strain rates. This can be understood from the consideration of a constitutive equation of the form:

$$\dot{\epsilon} = \frac{A\Omega D_{\text{eff}}}{kTd^3} \sigma + K\sigma^n \quad (\text{Eq 4})$$

(a)

(b)

**Fig. 5** Stress-strain curves at various constant strain rates for (a) Ti-6Al-4V at 927 °C (1701 °F) and (b) 7475 aluminum alloy at 516 °C (961 °F). Initial grain size: approximately 10 to 14 μm (395 to 550 μin.)

(a)

(b)

**Fig. 6** Grain growth kinetics at four different tensile strain rates compared with static kinetics for (a) Ti-6Al-4V at 927 °C (1701 °F) with 6.4 μm (250 μin.) initial grain size and (b) 7475 aluminum at 515 °C (959 °F)

where  $A$  is a constant,  $\Omega$  is the atomic volume,  $D_{\text{eff}}$  is the effective diffusion coefficient,  $k$  is Boltzmann's constant,  $T$  is absolute temperature,  $K$  is the constant for power-law creep (containing dependencies on temperature and shear modulus), and  $n$  is the power-law creep exponent. Li et al. (Ref 43) provided a detailed analysis of this effect for aluminum-magnesium superplastic alloys. Grain growth increases the proportion of strain contributed by dislocation creep, which reduces the value of  $m$  and causes flow hardening. Designating  $(A\Omega D_{\text{eff}}/kT)$  by  $A'$ , and if dynamic grain growth is given by  $d \sim d_0 t^p$ , the diffusional creep portion can be rewritten as:

$$\dot{\epsilon}_d = \frac{A'\sigma}{d_0^3 t^{3p}} \quad (\text{Eq 5})$$

where  $d_0$  refers to the initial grain size. During the step strain-rate test with constant strain-rate segments, if a stress of  $\sigma_1$  is obtained at a strain rate  $\dot{\epsilon}_1$  and a strain of  $\epsilon^1$ , and  $\sigma_2$  at  $\dot{\epsilon}_2$  and  $\epsilon_2$ , from Eq 4, then:

$$\frac{\sigma_2}{\sigma_1} = \left(\frac{\epsilon_2}{\epsilon_1}\right)^{3p} \left(\frac{\dot{\epsilon}_2}{\dot{\epsilon}_1}\right)^{(1-3p)} \quad (\text{Eq 6})$$

because  $t = \epsilon/\dot{\epsilon}$  for a constant strain-rate test. The strain-rate sensitivity  $m$  can be given by:

$$m = \frac{\log\left(\frac{\sigma_2}{\sigma_1}\right)}{\log\left(\frac{\dot{\epsilon}_2}{\dot{\epsilon}_1}\right)} = (1-3p) + 3p \frac{\log\left(\frac{\epsilon_2}{\epsilon_1}\right)}{\log\left(\frac{\dot{\epsilon}_2}{\dot{\epsilon}_1}\right)} \quad (\text{Eq 7})$$

Therefore, the amount of strain accumulated in each strain-rate step will influence the value of  $m$  through its influence on dynamic grain growth kinetics. If  $p = 0.25$  (Ref 30), then in the limit,  $m$  could vary between 0.25 and 1 and may be responsible for the apparent threshold stresslike behavior at low strain rates. The concurrent grain-growth-induced hardening thus makes it difficult to describe superplastic flow behavior accurately.

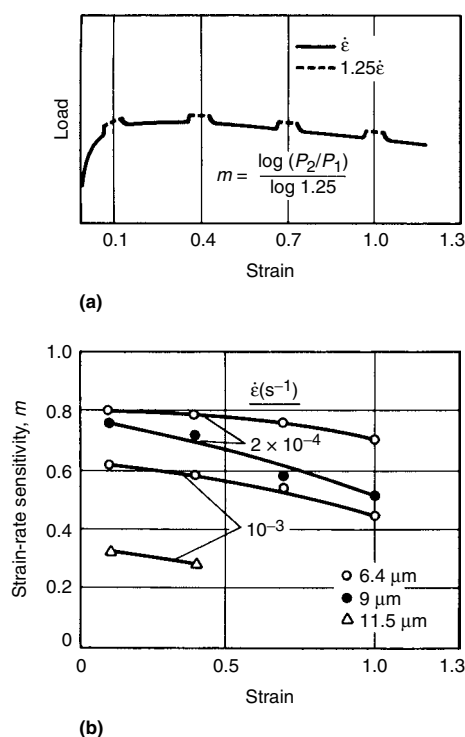

Step strain-rate tests conducted with minimum strain accumulation are used as the initial stress-strain-rate behavior of the material, and the strain-hardening component is measured and added separately. The rationale for this is seen in Fig. 7, in which two step strain-rate tests con-

**Fig. 7** Stress versus strain-rate plots for 6.4  $\mu\text{m}$  (250  $\mu\text{in.}$ ) grain size Ti-6Al-4V at 927  $^{\circ}\text{C}$  (1701  $^{\circ}\text{F}$ ) initially (that is, up to  $\epsilon = 0.17$ ) and after a strain of 0.45 at a rate of  $2 \times 10^{-4} \text{ s}^{-1}$  showing the hardening contribution due to the deformation

ducted with intermediate superplastic deformation clearly show that the hardening effect is not negligible. Although it may not be obvious from the slopes of these plots that  $m$  is also influenced by strain, a drop in  $m$  occurs due to concurrent grain growth (Fig. 3). The strain dependence of  $m$  can also be determined during constant strain-rate tests by making incremental strain-rate changes (Fig. 8a) of a small magnitude. With strain-rate changes of 25 to 40% maintained over a 2 to 3% plastic strain, the microstructure may not be altered significantly after return to the original strain rate. Figure 8(b) shows the decrease in  $m$  measured from these tests. Similar results have also been observed in aluminum alloys (Ref 44). The drop in  $m$  is usually more rapid at the higher strain rates and may be related to classical hardening due to dislocation buildup, which is also faster at high strain rates. Even though strain hardening has important implications for superplastic flow, the rate sensitivity of strain hardening is usually small, and  $m$  is still the parameter of greater interest. The article "Constitutive Equations" in this Volume shows extensive details and data on concurrent grain growth during superplastic deformation and its role in altering strain-rate sensitivity of alloys.

Important considerations in the selection and use of a superplastic alloy are the total elongation capability, the stability of the superplastic microstructure at high temperature, the latitude

**Fig. 8** Schematic representation (a) showing how instantaneous measurements of  $m$  can be made at periodic intervals during the tensile test by strain-rate increments of 25%. (b) Corresponding  $m$ -value as a function of strain for Ti-6Al-4V at 927  $^{\circ}\text{C}$  (1701  $^{\circ}\text{F}$ )

of the temperature and strain-rate range over which superplasticity is observed, and the rate of development of cavitation during superplastic deformation. All of these factors can change from lot to lot of the material, and it is generally advisable to check each lot for the superplastic properties as well as design properties. Information on superplasticity in specific materials is available in the articles "Forming of Aluminum Alloys" and "Forming of Titanium and Titanium Alloys" in this Volume.

## Superplastic Forming Processes

A number of methods and techniques have been reported for forming superplastic materials, each of which has a unique capability and develops a unique set of forming characteristics (Ref 3, 45). The following are forming methods that have been used with superplastic alloys:

- Blow forming
- Vacuum forming
- Thermoforming
- Deep drawing
- Superplastic forming/diffusion bonding (DB)
- Forging
- Extrusion
- Dieless drawing

Only those processes that relate to sheet metal forming are described in this section. Superplasticity as related to bulk forming operations is discussed in the section "Superplasticity in Iron-Base Alloys" in this article and in the article "Isothermal and Hot-Die Forging" in *Metalworking: Bulk Forming*, Volume 14A of *ASM Handbook*, 2005.

**Blow forming and vacuum forming** are basically the same process (sometimes called stretch forming) in that a gas pressure differential is imposed on the superplastic diaphragm, causing the material to form into the die configuration (Ref 3, 45–47). In vacuum forming, the applied pressure is limited to atmospheric pressure (that is, 100 kPa, or 15 psi), and the forming rate and capability are therefore limited. With blow forming, additional pressure is applied from a gas pressure reservoir, and the only limitations are related to the pressure rating of the system and the pressure of the gas source. A maximum pressure of 690 to 3400 kPa (100 to 500 psi) is typically used in this process.

The blow forming method is illustrated in Fig. 9, which shows a cross section of the dies and forming diaphragm. In this process, the dies and sheet material are normally maintained at the forming temperature, and the gas pressure is imposed over the sheet, causing the sheet to form into the lower die; the gas within the lower die chamber is simply vented to atmosphere. The lower die chamber can also be held under vacuum, or a back pressure can be imposed to suppress cavitation if necessary. The use of back pressure to control or prevent cavitation is discussed in the sections "Pressure Profiling" and

"Cavitation and Cavitation Control" in this article.

The rate of pressurization is normally established such that the induced strain rates in the forming sheet are maintained in the superplastic range. The rate of pressurization is determined by trial and error or by the application of analytical modeling methods (Ref 48–51). This pressure is generally applied slowly rather than

abruptly in order to prevent too rapid a strain rate and consequent rupturing of the part.

The periphery of the sheet is held in a fixed position and does not draw-in, as would be the case in typical deep-drawing processes. It is common to use a raised land (seal bead) machined into the tooling around the periphery, as shown in Fig. 10, to secure the sheet from slippage and draw-in and to form an airtight seal

in order to prevent leakage of the forming gas. Therefore, the sheet alloy stretches into the die cavity, and all of the material used to form the part comes from the sheet overlying the die cavity. This results in considerable thinning of the sheet for complex and deep-drawn parts, and it can also result in significant gradients in the thickness in the finished part.

This process is being widely used to fabricate structural and ornamental parts from titanium, aluminum, and other metals. An example of the process applied to the forming of a titanium aircraft nacelle frame is illustrated in Fig. 11 (Ref 52). In this case, the forming is conducted at approximately 900 °C (1650 °F), and inert gas (argon) is used on both sides of the sheet to minimize oxidation and related detrimental surface degradation due to the reactivity of titanium. The use of such protective gases is not usually necessary for aluminum alloys.

Large, complex parts can be readily formed by this method; it has the advantage of no moving die components (that is, no double-acting mechanisms) and does not require mated die components. Multiple parts can be formed in a single process cycle, thus permitting an increase in the production rate for some parts.

**Thermoforming methods** have been adopted from plastics technology for the forming of superplastic metals, and these methods sometimes use a moving or adjustable die member in conjunction with gas pressure or vacuum (Ref 46, 47, 53). Figure 12 shows two examples of thermoforming methods. In Fig. 12(a), an undersized male die punch is used to stretch form the superplastic sheet, followed by application of gas pressure to force the sheet material against the configurational die to complete the shaping operation. In Fig. 12(b), the first step involves blowing a bubble in the sheet away from the tool.

**Fig. 9** Schematic of the blow forming technique for superplastic forming

**Fig. 10** Various sealing methods that have been used around the sheet to provide a pressure seal suitable for containing the gas pressure during forming. Sections (a) and (b) use seal beads machined into the tooling, and (c) shows the use of a superplastic frame used as a soft gasket.

**Fig. 11** Ti-6Al-4V aircraft nacelle frame that was redesigned from a conventional configuration to one suitable for superplastic forming having fewer parts and fasteners. The redesigned version of this B-1B aircraft component, having 0.161 m<sup>2</sup> (250 in.<sup>2</sup>) plan view area, resulted in a 33% weight savings and a 55% cost savings over a conventional multiple-piece assembly.

The male tool is then moved into the bubble, and the pressure is reversed to cause the bubble to conform to the shape of the tool.

Figure 13 illustrates two other methods that employ a movable die member that aids in pre-stretching the sheet material before gas pressure is applied. In this case, the gas pressure is applied from the same side of the sheet as the moving die. These techniques provide ways of producing different shapes of parts and are effective for controlling the thinning characteristics of the finished part.

**Deep Drawing.** Although deep-drawing studies have been conducted with superplastic materials, this process does not appear to offer many significant advantages in the forming of superplastic materials. Deep drawing depends on strain hardening to achieve the required formability and to prevent thinning and rupture during forming. Superplastic materials do not strain harden to any great extent, but they depend on the high strain-rate hardening for their forming characteristics, and this property seems to offer little aid to deep drawing.

The difficulty is that, in order to draw-in the flange, the material in contact with the punch nose, as well as that in the sidewall, must work harden to carry the increasing stresses required to draw-in increasing amounts of the flange. At superplastic temperatures, no significant work hardening occurs, and the punch typically

pierces the blank, or the blank fails in the cup walls if the frictional constraint between the punch and the blank is high. However, in studies on the zinc-aluminum alloy, a maximum draw ratio of 2 to 1 has been developed under optimized conditions (Ref 54).

A technique that tends to improve the drawability of superplastic alloys is discussed in Ref 55. This method (Fig. 14) uses a punch cooled to a temperature below that of the forming blank, while the hold-down tooling is maintained at the forming temperature. It was demonstrated that this differential temperature technique permitted an increase in the limiting draw ratio from less than 2.4 to 1 for isothermal conditions to more than 3.75 to 1 for the differential temperature method. The thinning characteristics for this process are also shown in Fig. 14. Slight thinning can be seen to occur over the (cold) punch nose, and substantial thinning is seen in the material adjacent to the punch. The extent of the thinning in the material adjacent to the punch depends on the blank hold-down load but increases with increasing blank diameter (draw ratio) and decreasing punch speed. Because ironing was not used in these forming tests, thickness increases were observed at the greater distances from the pole of the cup where substantial draw-in of the material occurred.

Another concept evaluated to explore the deep-drawing capability is discussed in Ref 56. This method uses high-pressure oil around a blank periphery to aid in the drawing. It is actually a combined extrusion and drawing process. In this study, a tin-lead eutectic was used, which permitted processing at ambient

temperature. Good control of wall thickness was achieved, but the applicability of the process to alloys requiring high temperatures has yet to be demonstrated.

**SPF/DB Processes.** It is now well established that a number of unique processes are available if joining methods, such as diffusion bonding, can be combined with superplastic forming; these processes are generally referred to as SPF/DB processes (Ref 45, 56, 58). Although diffusion bonding is not a sheet metal process, it complements and enhances superplastic forming to such an extent that the two processes must be discussed together.

The SPF/DB processes evolved as natural combinations of the SPF and DB processes because the process temperature requirements of both are similar. The low flow-stress properties characteristic of the superplastic alloys aid the DB pressure requirements, and it has been found that many superplastic alloys can be diffusion bonded under pressures in the same low range as that used for SPF processing (that is, of the order of 2100 to 3400 kPa, or 300 to 500 psi). The SPF method used with SPF/DB to date is commonly blow forming.

The resulting SPF/DB process consists of the following variations:

- Forming of a single sheet onto preplaced details, followed by diffusion bonding (Fig. 15)
- Diffusion bonding of two sheets at selected locations, followed by the forming of one or both into a die (Fig. 16); the reverse sequence can also be used

**Fig. 12** Examples of thermoforming methods used for superplastic forming. (a) Plug-assisted forming into a female die cavity. (b) Snap-back forming over a male die that is moved up into the sheet

(a) Plot showing thinning characteristics of a 59.9 mm (2.36 in.) diameter Zn-21Al-1Cu-0.1Mg heated sheet that was formed using the 160 mm (6.3 in.) diameter water-cooled punch setup illustrated in (b) and (c).  $N$ , blankholder load. Both the die and zinc alloy sheet were heated to 230 °C (445 °F). Punch speed was 33.0 mm/min (1.3 in./min), and maximum punch load was 2150 N (483 lbf). Draw ratio was 3.75. See text for discussion.

**Fig. 15** Cross section of the superplastic forming (SPF) process combined with diffusion bonding (SPF/DB). The process shown uses preplaced details to which the superplastic sheet is bonded.

- Diffusion bonding of three or more sheets at selected locations under gas pressure, followed by expansion under internal gas pressure, which forms the outer two sheets into a die; in the process, the center sheet(s) is stretched into a core configuration (Fig. 17)

A few techniques have been used to develop diffusion bonds in predetermined local areas. One of these involves the use of a parting agent, or stop-off material, between the sheets in the local areas where no bonding is desired. Suitable stop-off materials may depend on the alloy being

bonded and the temperature being used. For example, yttria or boron nitride has been successfully employed to stop-off titanium alloys processed to temperatures of at least 930 °C (1705 °F). Such stop-off materials can be suspended in an appropriate binder, such as acrylic. After a DB operation, the area of the stop-off pattern is not bonded, and gas can be applied internally along this pattern, thus causing the external sheets to be separated and formed by expanding into a surrounding die.

A variation of the aforementioned method involves the use of a minimum of four sheets to

**Fig. 16** Operations required for joining two sheets of superplastic alloy using the superplastic forming/diffusion bonding process

make a sandwich panel. The external (for example, skin) sheets are expanded, the inner two sheets are then bonded (or welded) to define the core structure, and finally the core is expanded to bond with the external sheets and to complete formation of the sandwich structure. This sequence is shown in Fig. 18.

## Forming Equipment and Tooling

The forming of superplastic sheet materials involves methods that are generally different from those used in other, more conventional sheet forming processes. The forming environmental conditions are also different. Therefore, the equipment and tooling used are generally different.

**Forming Equipment.** For the blow forming and vacuum forming methods, there is a need to provide constraint to the forming tools in order to counteract the forming gas pressure. In addition, a seal is generally required at the interface between the sheet and the tool around the periphery in order to prevent leakage of the gas pressure. A press is typically used to meet these requirements. Hydraulic presses and mechanical clamping systems have been used, and each has advantages and disadvantages. The hydraulic press can be loaded and unloaded fairly rapidly, but it requires a significant capital investment. The mechanical clamping systems are much less expensive but are more cumbersome to load and unload. Recently, robotic systems have been coupled with a hydraulic press to aid the loading and unloading, and this type of advanced system is especially beneficial for high-temperature forming operations such as titanium alloy SPF processing.

The hydraulic presses used include both single-action and multiple-action systems (Ref 45, 46, 53). In the single-action press, the press applies the constraining pressure only. In the multiple-action press, the press can also move

dies into the forming sheet and effectively aid in the control of the thinning gradients (Fig. 12, 13).

The heating system used must be tailored to the temperature required and the allowable thermal gradients. The most common heat source is electrical heating, in which resistance heating elements are embedded in ceramic or metal pressure plates placed between the tooling and the press platens. This allows for good control of the temperature and provides a clean source of energy. The heating platens can be arranged in sections of heating elements, and each section can be controlled by independent temperature controllers to minimize thermal gradients in the forming die assembly. Significant thermal gradients can lead to excessive thinning or rupture of the sheet during forming.

**Tooling Materials.** The tooling used in the SPF process is generally heated to the forming temperature, and it is subjected to internal gas pressure and pressing clamping loads. The internal gas pressure is typically less than approximately 3400 kPa (500 psi), and this is usually not the critical design factor for SPF tools. More important are the clamping loads and thermal stresses encountered during heatup and cooldown and the environmental conditions. The thermal stresses can cause permanent distortions in the die, and this is controlled by selection of a material that has good strength and creep resistance at the forming temperature. Slow heating and cooling of the tooling can reduce the thermal stresses. Materials with a low coefficient of thermal expansion and those that do not undergo a phase transformation during heating and cooling are preferred for the high-temperature SPF processes.

The environmental conditions can be severe for the forming of high-temperature materials, such as the titanium alloys, iron alloys, nickel

alloys, and other high-temperature metals. Oxidation can alter the surface condition of the tooling, thus affecting the surface quality of the SPF part produced and eventually affecting the dimensional characteristics.

Another important environmental factor is the compatibility between the superplastic sheet and the tooling, and the compatibility of these with the stop-off materials that may be used. Interdiffusion at the tooling/sheet interface can result in the degradation of both of these materials. Reactive metals, such as titanium alloys, are especially prone to this type of problem. Tooling materials that have been found to be successful with titanium alloys are the Fe-22Cr-4Ni-9Mn alloy and similar materials. Parting, or stop-off, agents are also helpful in minimizing the interaction, and materials such as boron nitride and yttrium oxide have been successfully used. Generally, materials with a low solid solubility in the sheet are good candidates for compatibility.

A variety of materials have been used for SPF tooling, including metals and alloys, ceramics, and graphite (Ref 59). Metal tools, such as H-13 tool steels, are good for forming aluminum parts and are preferred for large production quantities, such as 100 parts or more. Graphite tools are suitable for approximately 100 parts, and they are readily hand worked, although there is a problem with shop cleanliness with graphite. Ceramics can be cast into the desired shape and are therefore inexpensive for a variety of large parts. Because the ceramic is subject to cracking and rapid degradation, it requires frequent repair. Ceramic tools are considered for small production quantities, usually less than approximately 10 parts.

**Fig. 17** Operations required for joining three sheets of superplastic alloy using the superplastic forming/diffusion bonding process

**Fig. 18** Example of a four-sheet superplastic forming/diffusion bonding process in which the outer sheets are formed first and the center sheets are then formed and bonded to the outer two sheets

## Thinning Characteristics

To take advantage of the very high elongations possible with superplastic metals, it is necessary to accept the accompanying significant thinning in the sheet material. This thinning is a natural consequence of the deformation conditions. For superplastic deformation, elastic strains are negligible; therefore, constancy of volume can be assumed. From this consideration, the sum of the plastic strains is 0, and tensile strain in one direction must be balanced by compressive (negative) strains in another. The strains are:

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0 \quad (\text{Eq } 8)$$

where  $\epsilon$  is the strain, and the subscripts indicate the principal directions. For example, in a sheet forming operation under plane-strain conditions,  $\epsilon_2 = 0$  and  $\epsilon_3 = -\epsilon_1$ . In this case, the thinning strain (for example,  $\epsilon_3$ ) is equal and opposite to the longitudinal tensile strain, and the thinning will therefore match the tensile deformation. For large tensile strains, the thinning will be correspondingly large. Accordingly, as the thinning increases, the tendency to develop thinning gradients also increases.

Although superplastic materials are effective in resisting the necking process, they nonetheless do neck (in relation to the  $m$ -value), and thinning gradients do develop. Therefore, in the design and processing of SPF parts, it is important that the thinning be understood and considered.

**Uniaxial Tensile Test.** It has been shown that superplastic deformation occurs when  $m$  is large and that under these conditions the deformation process is predominately postuniform, in contrast to conventional metal tensile behavior. In most cases, virtually all deformation is non-uniform, and the issue in the tensile behavior is the extent of this nonuniformity. The thinning in the tensile specimen can be assumed to be the result of a preexisting inhomogeneity, which can grow under the imposed deformation (Ref 60, 61).

The rate of thinning in the tensile specimen is therefore determined not only by the size of the inhomogeneity but also by the  $m$ -value. This has been demonstrated analytically for an idealized tensile specimen (Fig. 19) containing a

**Fig. 19** Geometric inhomogeneity,  $f$ , in a tensile specimen

geometric inhomogeneity,  $f$  (for example, a machining defect) (Ref 30). This analysis follows the strain development both inside and outside the inhomogeneity, assuming that the applied load is fully transferred along the length of the specimen and that the material obeys the following constitutive equation:

$$\sigma = K \dot{\epsilon}^n \dot{\epsilon}^m \quad (\text{Eq 9})$$

where  $n$  is the strain-hardening exponent ( $n$  is small in this case). The results of calculations using Eq 9 are shown in Fig. 20, in which the strain in the inhomogeneity is graphed as a function of the strain outside the inhomogeneity for a number of different  $m$ -values. The extent of the thinning in the tensile specimen is shown to be strongly related to the  $m$ -value, although thinning gradients will develop at all  $m$ -values if

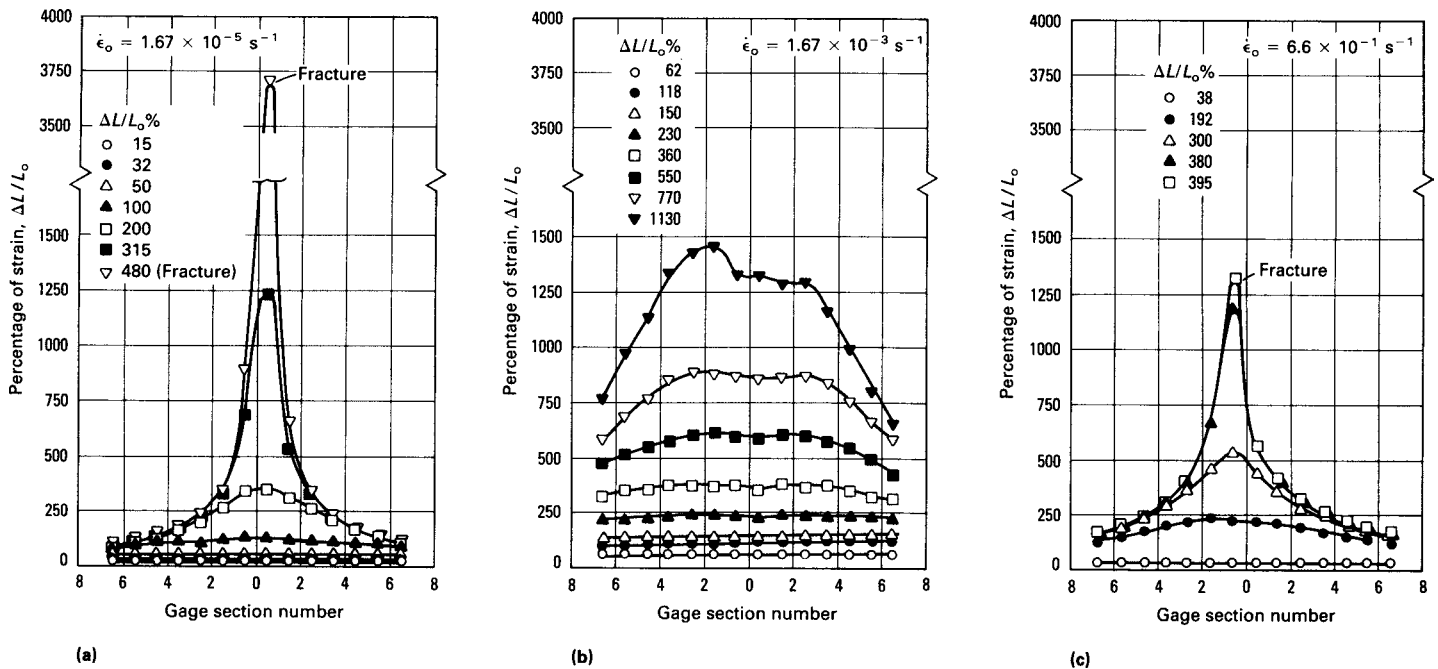

**Fig. 20** Calculated strains inside and outside an inhomogeneity in a tensile specimen, such as that shown in Fig. 19, for various  $m$ -values

the strain is sufficiently large. It will be seen that this is also the case for sheet forming in which the inhomogeneity is caused by stress gradients resulting from the part geometry and tool interactions. The inhomogeneities in tensile specimens have also been found to relate to the  $m$ -value (Ref 62), as shown in Fig. 21 for the Zn-22Al eutectoid alloy. In Fig. 21, the results are presented for the same alloy tested at different strain rates, for which the  $m$ -values are known to differ.

**Spherical Domes.** Although the thinning in superplastic tensile test specimens is the result of geometric inhomogeneities, the corresponding thinning in biaxially formed parts is usually the result of local stress-state differences, which subsequently lead to the development of geometric inhomogeneities. In all of these cases, however, the difference in the local stresses leads to strain-rate gradients, and the strain-rate gradients develop directly into thickness gradients. A major difference between the tensile specimen and the part configuration is that, in the former, the stress gradients can be varied (that is, reduced) by dimensional control during machining. In part forming, however, the configuration determines the stress state, and the stress state is not adjustable without changing the geometry.

The concept of thinning during SPF processing is perhaps best understood in terms of the bulging of a sheet (Ref 48, 49, 53, 63–69). In this geometry, there is a stress-state gradient from the pole of the dome to the edge, as shown in Fig. 22. If the dome is assumed to develop into a part of spherical symmetry, the stress state can be

**Fig. 21** Local elongation gradients in tensile specimens of Zn-22Al alloy at  $T = 473$  K with initial gage length  $L_0$  of 12.7 mm (0.500 in.) that were tested within the superplastic strain-rate range (b) and outside the superplastic strain-rate range (a) and (c). The total percentage of strain at each termination point is given by  $\Delta L/L_0$ , where  $\Delta L$  is the overall increase in gage length. The percentage of strain in each of the 14 individual segments of the gage length is given by  $\Delta L/L_0(\%)$ , where  $\Delta L$  is the increase in length of each small segment of the specimen. The initial strain rate was  $\dot{\epsilon}_0$ .

readily described. At the pole, the orthogonal stresses are equal, and the stress state is that of equibiaxial tensile. At the edge of the dome, there is constraint around the periphery, leading to a plane-strain stress state. Because the flow behavior of superplastic metals has been often found to obey the von Mises criterion (Ref 70), it is helpful to examine the effective stress,  $\bar{\sigma}$ , which will determine the corresponding strain rate:

$$\bar{\sigma} = \frac{1}{\sqrt{2}} [(\sigma_\theta - \sigma_\phi)^2 + (\sigma_\phi - \sigma_r)^2 + (\sigma_r + \sigma_\theta)^2]^{1/2} \quad (\text{Eq 10})$$

If it is assumed that the through-thickness stress is small with respect to the in-plane stresses, the effective stresses at the pole and the edge can be expressed in terms of the meridional stress,  $\sigma_\theta$ , as follows:

$$\bar{\sigma}_p = \sigma_\theta$$

and

$$\bar{\sigma}_e = \frac{\sqrt{3}}{2} \sigma_\theta = 0.87 \sigma_\theta \quad (\text{Eq 11})$$

where the subscripts  $p$  and  $e$  indicate the pole and the edge, respectively, of the dome. Therefore, the pole is experiencing a 15% higher flow stress than the edge, resulting in a higher strain rate, the initial magnitude of which depends on the  $m$ -value.

The stress-state difference between the pole and the edge of the dome is roughly the equivalent of a tensile specimen, which has a local geometric inhomogeneity,  $f$ , of 0.13. The initial strain-rate difference between these two areas is dependent on the  $m$ -value; the larger the  $m$ -value, the smaller the strain-rate difference and the less the tendency to develop a thickness gradient. For example, the ratio of  $\dot{\epsilon}_e/\dot{\epsilon}_p$  is 0.87 for  $m = 1$ , and the value is 0.5 for  $m = 0.2$ , both for the same initial effective stress difference.

Therefore, the stress gradient in a forming dome causes a more rapid thinning rate at the pole, and it may be expected that the thinning difference will accelerate with time, leading to a thickness gradient in the formed dome. There are abundant experimental results to show that this is the case and that the thinning gradient is a function of the  $m$ -value. Profiles of thickness

Fig. 22 Illustration of a spherical dome indicating the range of stress states existing between the pole and the edge

for bulge-formed sheets are shown in Fig. 23 for  $m$ -values of 0.57 and 0.23 (Ref 63). The thickness gradient is in agreement with expectations, and the effect of the high  $m$ -value in impeding localized thinning at the pole can be seen. Other results for a titanium alloy and a stainless steel for which  $m$ -values are 0.75 and 0.4, respectively, are shown in Fig. 24, in which the thickness strain is plotted as a function of the position along the dome cross section (Ref 44). The position along the dome is measured as the fractional height,  $h/h_0$ , where  $h_0$  is the full height of the dome, and  $h$  is the height on the dome at which the thickness measurement is made.

A number of analytical developments have been reported that predict the thinning for the superplastic forming of this type of geometry (Ref 49, 53, 65, 67–69). These models result in relations for thicknesses that are not closed-form but require numerical integration of strain increments. The models predict the thinning characteristics reasonably well, as can be seen by the comparison of experimental and analytical data shown in Fig. 24 and 25.

The theoretical predictions can be used to show the influence of the strain-rate sensitivity of

Fig. 23 Experimentally observed thickness profiles for a hemispherical dome formed from materials with two different  $m$ -values (solid lines). The smaller, broken outlines confined mainly within the experimental data silhouette represent bulge profiles (1) and sheet thickness distributions (2) that were calculated using (a)  $m = 0.50$  and (b)  $m = 0.20$ .

Fig. 24 Thickness strain as a function of the fractional height for dome-shaped parts formed from a stainless steel with an  $m$ -value of 0.4 and a titanium alloy with an  $m$ -value of 0.75. The values  $s$  and  $s_0$  in  $\ln(s/s_0)$  represent dome thickness and initial sheet thickness, respectively.

flow stress on the thinning gradient. For example, the thinning for a hemisphere formed from materials of differing  $m$ -values is illustrated in Fig. 25. In Fig. 25, the thinning factor  $s/\bar{s}$  is plotted as a function of the fractional height, where  $s$  is the local thickness, and  $\bar{s}$  is the average dome thickness. The maximum thinning occurs at the pole because of the stress state, as mentioned previously, and the strain-rate sensitivity is a crucial parameter in determining not only the initial strain-rate difference but also the subsequent rate of thinning, as shown in Fig. 26, in which the thinning factor at the pole can be seen to be increasingly influenced by  $m$  as the dome height is increased.

The initial stress-state differences and the corresponding strain-rate differences along the meridian of a forming dome lead to a predictable thinning gradient in this type of geometry.

Fig. 25 Theoretical relations for a hemisphere showing the thinning factor as a function of the fractional height for a range of  $m$ -values from 0.3 to 1.0

Fig. 26 Theoretical curves showing the thinning factor at the pole as a function of the bulge height-to-base ratio for  $m = 0.3, 0.5$ , and  $0.75$

The magnitude of the thinning gradient, however, is determined by the strain-rate sensitivity,  $m$ , and the height to which the part is formed.

**Rectangular Shapes.** The factors that contribute to the thinning characteristics in rectangular parts, as well as other shapes, are the same as those for the spherical dome-shaped parts discussed in the previous section in this article. It is the specific geometry that determines the initial stress-state gradients, and different geometries will be expected to develop different stress states in the forming part.

The rectangular shape is one that is common to many parts or sections of parts; therefore, it has been studied by experimental and analytical methods similar to those used for the spherical dome (Ref 45, 50, 70). For the long rectangular shape, there is a plane-stress state throughout the width of the sheet; for the case in which the die entry radius does not cause a significant stress concentration, the sheet will not experience an initial stress-state gradient. This case is very similar to that of the tensile test, in which only thickness variations or material inhomogeneities will cause local stress differences leading to localized thinning. Because these are small in comparison to the magnitude of the stress variation in the forming dome, it may be expected that the thinning gradients would be less pronounced. Experimental results for the free-forming cylindrical section show this to be the case, as illustrated in Fig. 27, and virtually no thinning gradient is seen for hemicylindrical shapes.

Interactions with the tooling do, however, cause local stress variations that can lead to thinning gradients, as shown in Fig. 27. This effect can be considered as two different types resulting from different areas of the die—the die surface at the bottom and sidewall, and the die entry radius.

**Die Bottom and Sidewall.** Ignoring the die entry effects, the die surface can be considered to restrict deformation in the forming sheet where contact has been made and where friction is nonzero. If the friction is large, the forming characteristic is as illustrated in Fig. 28. When the sheet makes contact with the die wall surface, the deformation in that contact area is restricted, and thinning is localized in the noncontact areas, leading to a greater degree of thinning in the last area to contact the die than in the first areas to make contact (Fig. 28). This results in a thickness gradient, as shown in Fig. 29, for a titanium alloy part formed in a die with no lubricating compounds present.

This type of thinning is readily predicted analytically if it is assumed that the sheet sticks to the die surface after contact is made by using an incremental method (Ref 50). Results of this type of model show that there are a variety of thinning variations corresponding to various width and depth ratios of the rectangular shape, as shown in Fig. 30. It is apparent from Fig. 30 that the narrow and deep parts develop the greatest amount of thinning. In this specific case,

the thickness profiles can be predicted quite well without referring to the strain-rate sensitivity,  $m$ . This is the result of the dominant effect of the die friction coupled with the uniform initial stress state.

If the interfacial friction is reduced, the thinning gradient will be reduced in the sidewall and bottom areas because continued deformation after die contact is possible. An example of the thinning in a formed rectangular titanium part is shown in Fig. 31, for which forming was conducted with a boron nitride solid lubricant (Ref 45, 50).

A *die entry radius* causes a local stress concentration in the forming sheet, which then creates a stress-state gradient in the forming sheet, and this can lead to localized thinning, especially if the ratio of die radius to sheet thickness is small and if the surface is lubricated. The source of the

stress concentration is the back pressure exerted by the die radius on the forming sheet and the gas pressure on the opposite side of the sheet from the die. The pressure exerted by the die radius has been shown to be (Ref 50):

$$P_r = \frac{\sigma_w h}{R_1} \quad (\text{Eq 12})$$

where  $P_r$  is the pressure on the die entry radius,  $\sigma_w$  is the in-sheet stress in the width direction,  $h$  is the sheet thickness, and  $R_1$  is the die entry radius.

**Fig. 27** Thinning development in a 1.37 mm (0.054 in.) thick superplastic formed Ti-6Al-4V part having a rectangular cross section and semi-infinite length. Formed at 870 °C (1600 °F) using a boron nitride lubricant, the sheet required 20 min to fabricate at an average strain rate of  $5.8 \times 10^{-4} \text{ s}^{-1}$ . Dimensions given in inches

**Fig. 28** Illustration of thinning characteristics in the blow forming of an unlubricated part of rectangular cross section and semi-infinite length

**Fig. 29** Observed and predicted thinning profiles in an unlubricated blow-formed Ti-6Al-4V alloy part of rectangular cross section. Forming of the sheet, which had an initial thickness of 1.68 mm (0.066 in.), required 20 min at 925 °C (1700 °F).

This and the applied gas pressure,  $g$ , develop an average through-thickness stress  $\sigma_h$  of:

$$\sigma_h = \frac{g + P_r}{2} \quad (\text{Eq 13})$$

The magnitude of  $\sigma_w$  will be dependent on the local friction coefficient,  $\mu_r$ , and the position on the radius, so that the effective stress will vary around the die entry radius. A detailed analytical model of this somewhat complex condition is available in Ref 50, but it has been shown that a local stress increase is developed in this area, causing a tendency toward local thinning. If the friction is sufficiently low, the initially thinned section can continue to thin after die contact is made. Therefore, significant localized thinning can occur, and even rupture may take place if the conditions are sufficiently severe.

Thinning over the die entry radius is the result of stress gradients; therefore, the strain-rate sensitivity  $m$  is an important parameter in determining the extent of thinning that will develop. The influence of these variables is illustrated in Fig. 32 for a titanium alloy part formed under the indicated conditions of lubrication and strain rate. The strain-rate variations resulted in corresponding variations in the  $m$ -value during the respective forming process. The thinning for the unlubricated part is in agreement with that expected from the discussion in the previous section in this article. For this case where lubricant is used, the strain rate, which determines the corresponding  $m$ -value, is a factor in determining the extent of thinning over the die entry radius. The average  $m$ -value corresponding to the die entry radius was higher for the forming process that developed the lower average strain rate, resulting in a significantly reduced tendency toward local thinning in that area.

**Thinning Control.** Because SPF parts are typically stretched to very large elongations, the thickness variations are potentially large for a part. Therefore, it is often important to control

the thickness variations in order to meet part tolerance requirements. Although it is seldom possible to prevent thickness variations, there are techniques that can be used to control this problem. In addition to such methods, the designer can often accommodate variations in thickness if he knows in advance what they may be. This latter approach is an important and viable one but is not addressed in this article because it is a very specialized field of metallurgy.

The methods used to control thinning are:

- Processing of the superplastic material to achieve a high  $m$ -value
- Use of surface lubrication, as discussed previously
- Use of thermoforming methods to control the localized deformation
- Modification of the die or part design to minimize local stress concentrations
- Forming a thickness-profiled sheet
- Application of pressure in a controlled and profiled manner to control strain rate to a value corresponding to a high  $m$ -value

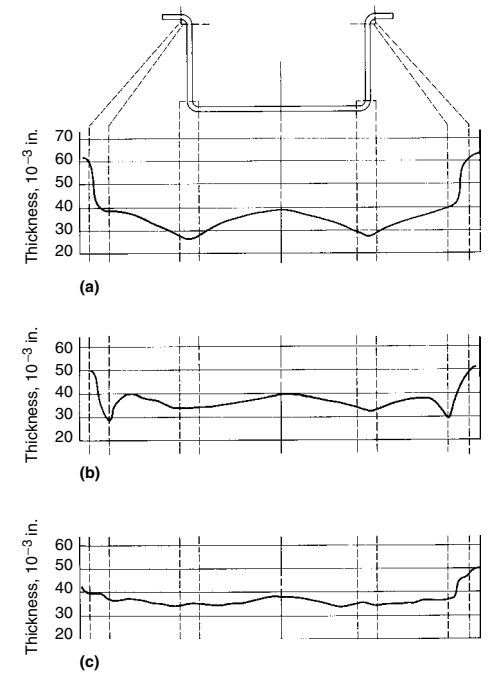

Because the raw sheet material is generally obtained from a commercial supplier, the material superplastic properties are under the control of the mill. However, it may be judicious for the forming plant to obtain material under the control of an appropriate specification. The effect of lubrication is discussed in the section "Die Entry Radius" in this article, along with the effect of the die entry radius, which may, in some parts, be increased to minimize the thickness gradients.

The thermoforming method has been shown to offer effective techniques that can control the thinning gradients in single-pocketed deep-drawn parts (Ref 47, 53). With these methods, a movable tool is usually used to contact the forming sheet before the finished shape is produced, causing the local friction to minimize deformation in some locations while free-forming sections continue to deform.

The use of thermoforming techniques was demonstrated using apparatuses such as those shown in Fig. 33 and 34 (Ref 53). The test rig used consisted of two cylindrical chambers, each 190 mm (7.5 in.) in inside diameter by 178 mm (7 in.) deep, and a hydraulic ram, positioned in the bottom chamber, that was capable of moving up and down. The material used was Zn-22Al-0.15Cu sheet 1.27 mm (0.050 in.) thick. For the convex upward die, the deformation was restricted in the center of the sheet and concentrated at the outer area, resulting in a strain and thickness profile, as shown in Fig. 35, in which the top center is thicker than the adjacent areas. This thickness profile was substantially modified by the use of a concave

**Fig. 30** Predicted minimum thicknesses as function of the width-to-depth ( $w/h$ ) ratio for unlubricated blow-forming part of rectangular cross section

**Fig. 31** Observed thickness profiles for 1.68 mm (0.066 in.) thick Ti-6Al-4V blow-formed parts of rectangular cross section formed under different average strain rates,  $\dot{\epsilon}_t$ , and with different lubrication conditions. (a)  $\dot{\epsilon}_t = -7 \times 10^{-4} \text{ s}^{-1}$ ; no lubricant. (b)  $\dot{\epsilon}_t = -5.6 \times 10^{-4} \text{ s}^{-1}$ ; boron nitride lubricant. (c)  $\dot{\epsilon}_t = -5.4 \times 10^{-5} \text{ s}^{-1}$ ; boron nitride lubricant

**Fig. 32** Observed thickness distribution for Ti-6Al-4V parts with 1.14 mm (0.045 in.) initial thickness at 927 °C (1700 °F) formed at  $10^{-3} \text{ s}^{-1}$  with boron nitride lubrication

upward die, as shown in the Fig. 36. In this case, the superplastic diaphragm was formed down into the concave die by gas pressure, and the die was slowly withdrawn until it reached the bottom. The preformed diaphragm was then formed into the upper cylindrical chamber in the same

manner as that of the previous figure. The resulting profile is seen to be considerably more uniform across the top of the part.

The use of thickness-profiled sheet has been suggested to control the thickness in the final part (Ref 67). The concept considers that the initial

thickness variations can be used to offset the subsequent variations resulting from the stress state and part geometry effects on the thinning, as shown in Fig. 37. If areas that will thin excessively are thicker than surrounding areas, it is possible to develop finished part thickness profiles that are more uniform than those formed of constant-thickness sheet.

**Pressure Profiling.** It is now well recognized that the  $m$ -value for superplastic alloys will vary with strain rate and that it will also often vary with strain. The strain rate imposed during the forming process will therefore determine the  $m$ -value, and if the strain rate varies during the forming process, the corresponding  $m$ -value and related thinning uniformity will also vary. For example, the simplest pressurization concept for SPF processing is that of constant pressure.

The resulting strain-rate variation for a spherical dome part configuration has been shown to be as much as 3 orders of magnitude (Ref 48). A graph of the predicted strain rate for a spherical dome that will be generated under constant pressure for such a part is shown in Fig. 38. The strain rate drops to 0.001 of the initial value when the part becomes a hemisphere. The  $m$ -value for a typical superplastic alloy can vary from a maximum  $m$  to a value of less than 0.2 over strain-rate ranges of this magnitude. The consequence of forming a part under these conditions is that excessive thinning or part rupture during forming is likely. The initial strain rate corresponds to a large  $m$ -value, and good thinning resistance is observed. However, this would be transient; other strain rates would be encountered corresponding to low  $m$ -values, and poor resistance to localized thinning would be present.

This condition can be rectified if the strain rate can be maintained at a constant level corresponding to a suitably high  $m$ -value. Because the constant pressure is seen to develop a variable strain rate, it is apparent that a variable forming pressure would be required to develop a constant strain rate. Such pressure profiles have been established analytically for the spherical dome (Ref 48, 49) and the rectangular (Ref 50) part configurations. Because most of the analytical models of the SPF process use applied gas pressure to establish the current stress and strain-rate conditions, it is possible to use these same models to adjust the current gas pressure to develop the desired stress and strain rate.

The resulting pressure profiles for the constant strain-rate forming of the spherical dome and the rectangular parts are illustrated in Fig. 39 and 40, respectively. It is typical that the pressure initially rises rapidly, followed by decrease. The rapid initial rise is due to a rapid decrease in the radius of curvature with little change in thickness, and the subsequent decrease is the result of thinning that is more rapid at this stage than the change in radius of curvature. The depth to which a part is formed will also affect the pressure profile for constant strain-rate control, as shown in Fig. 41 for a rectangular part formed with no lubrication. For a deep part ( $w = 305$  mm,

## Cavitation and Cavitation Control

Most superplastic alloys tend to form voids, or cavities, at intergranular locations during the superplastic deformation. This process is termed cavitation. Cavitation can lead to the degradation of strength and other design properties, and it is dealt with in one of two ways:

- Establishing reduced design properties
- Using a back-pressure technique to control cavitation

Typical cavitation as a function of strain is shown for an aluminum alloy in Fig. 42. It can be seen that the absolute amount of cavitation in terms of the volume fraction is not large but depends on the strain imposed. The use of the back-pressure concept imposes a hydrostatic pressure on the sheet during forming, and if this pressure is of the order of the flow stress, cavitation can be reduced or completely suppressed. An example of the effect of back pressure on the rate of development of cavitation is shown in Fig. 43.

In practice, the back pressure is achieved by imposing a pressure on the back side of the sheet to oppose the forming pressure and by sustaining this pressure during the forming cycle. The forming pressure must be higher than the back

pressure, and the same forming rates can be achieved with or without back pressure if the pressure differential is the same. For example, if a pressure profile is desired, such as that shown in Fig. 39 or 40, the pressure profile is simply raised in magnitude by an amount equal to the back pressure. Because the back pressure is normally of the order of the material flow properties, pressures of approximately 690 to 3400 kPa (100 to 500 psi) are generally suitable for suppressing cavitation.

## Manufacturing Practice

The SPF process is unique in terms of the complexity of parts that can be produced and the methods that can be used to shape such a material. A number of processing methods are currently being used, most of which involve significant stretching of sheet material. The high ductility that can be achieved with these types of materials also has a consequence that must be understood and dealt with, namely, thinning gradients. The thinning gradients are a natural consequence of stress gradients that develop in the various die configurations, and the superplastic property of the strain-rate sensitivity of the flow stress then determines the subsequent thinning gradient that will result in the part. Control of the forming process, die configuration, and material characteristics are all factors that can affect the thinning.

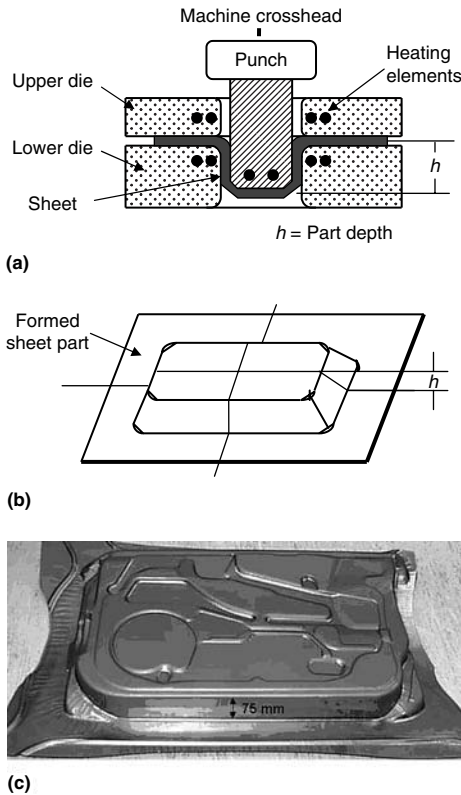

The SPF processes are being increasingly used for a wide range of structural and nonstructural applications. The aerospace industry depends greatly on the structural integrity of the parts, but the automotive industry uses body sheet metal parts that do not require very high structure strength, and cavitation can be tolerated. Under rapid forming conditions at low forming temperatures, cavitation in aluminum alloys is generally found (Ref 71–73). However, rapid forming technology is in great demand for improving the efficiency of the superplastic forming process. Faster forming rates are obtained by mated punch-die technology as in sheet stamping, rather than by gas pressure forming. This has led to the development of warm forming technologies, which use embedded heating elements in the punch and die systems. Figure 44 shows an arrangement for a heated die system for warm stamping of aluminum alloys. This has been developed with integrally embedded heating elements within punch-die systems rather than gas pressure forming systems. Part forming with 5083-type aluminum alloys has been demonstrated in less than a minute per part, and hundreds of parts have been produced (Ref 74, 75). Using warm forming technology, full-scale parts such as the Chrysler Neon inner door panel were successfully formed from fine-grain 5182 aluminum alloy containing 1% Mn at the rate of one minute per part (shown in Fig. 44c). This development, originally spearheaded by the U.S. Department of Energy in 2000, has spawned other rapid gas-pressure

forming technologies discussed in the next section.

### Quick Plastic Forming Cells

In terms of gas pressure forming, General Motors has concentrated on the rapid transfer of sheet between tooling, blank preheating, and the use of robotics in systems referred to as quick plastic forming cells. The quick plastic forming (QPF) system (Ref 76) was developed by General Motors to address the major deficiencies of the automated SPF system:

- Inefficient press utilization
- Inability to achieve the desired pressure/time cycle in the tool
- Inability to maintain the desired process temperature for short forming cycles
- Tool temperature variation
- Forming cell inflexibility

A forming cell configured with these characteristics would run with the process steps shown in Fig. 45. A forming cell capable of maintaining the desired forming temperature for very short cycles must incorporate tools of very high thermal conductivity, elaborate control systems, or tools with heating sources very close to the working surfaces. Further, improved

**Fig. 45** Operating process for purpose-built quick plastic forming cell

**Fig. 46** The quick plastic forming (QPF) process can be run with integrally heated dies as for warm forming applications.

methods to model the forming process were needed to facilitate application to products within the normal GM vehicle development timing. An integrated QPF cell was developed and demonstrated for a decklid inner panel.

### Purpose-Built QPF Cell Technology Elements

**Blank preheating** is done outside the press in a purpose-built oven. The preheating system has at least two additional advantages over the ability to support a faster process time. First, productivity of the press doubles over that of the in-press heating system, because the press space and time previously used for preheating can now be used for forming. Further, the faster heating rate may produce a material microstructure with better inherent formability.

**Improved Pressure/Time Control.** In typical QPF cycles, the gas flow rate increases substantially between the initial and final stages of panel forming. To allow for good pressure control at both high and low gas delivery volumes, QPF gas management systems are based on proportional control valves capable of adequate pressure resolution at low pressures but also of large-volume gas delivery at high pressures.

**Improved Thermal Control.** The heated die-tool system shown in Fig. 46 offers many advantages in performance and flexibility in terms of minimizing heat loss. One downside to

moving to heated and insulated tools is the increased cost and complexity of the tool system. However, the increased cost can be amortized over a larger number of panels due to the increase in system productivity. The higher tool cost is also partially offset in that the heating system can be run at a much lower temperature than the press heating system for a given tool temperature. Further, the convective and radiation losses of the heated tool system are much lower than the heated press system, and energy savings of 50 to 70% have been demonstrated in the QPF process.

**Improved Forming Cell Flexibility.** By developing the heated tool as a self-contained system fully enclosed in insulation, the tool package can be handled using ordinary means (cranes, lift trucks) without risk to the tool-change operators. The tool insulation system was developed to maintain an exterior surface temperature of <55 °C (130 °F). That temperature facilitates fast tool-change capability. Further, only very minor modifications are needed to allow the heated/insulated tool to be mounted to the press with existing automated clamping systems. A quick tool-change is possible with the heated-tool systems, and the newly installed tool is immediately available for forming because it can be preheated off-line.

The use of fully insulated tools and the accompanying fast tool-change capability allow a QPF press line to be run in a manner similar to a conventional press line; that is, a single line could support more than one product without significant downtime during tooling changeover.

### Superplasticity in Iron-Base Alloys\*

Superplasticity is the ability of certain polycrystalline metallic materials to extend plastically to large strains when deformed in tension. Strains to failure in superplastic materials range from several hundred to several thousand percent. In general, superplastic materials also exhibit low resistance to plastic flow in specific temperature and strain-rate regions. These characteristics of high plasticity and low strength are ideal for the manufacturer who needs to fabricate a material into a complex but sound body with a minimum expenditure of energy.

The phenomenon of superplasticity was first observed over 70 years ago (Ref 77), but active research in this field did not begin until 1962 (Ref 78). Since that time, superplastic effects have been reported in over 100 alloy systems (Ref 78). The micromechanisms that permit extraordinary elongations in these materials are still under investigation (Ref 79), but it is generally accepted that a major microstructural requirement for

\*Reprinted from "Appendix: Superplasticity in Iron-Base Alloys" by Oleg D. Sherby, Stanford University; Jeffrey Wadsworth, Lockheed Missiles and Space Company; Robert D. Caligiuri, Failure Analysis Associates, in *Forming and Forging*, Volume 14, *Metals Handbook*, 9th ed., ASM International, 1988, p 868-872.

superplasticity is the development of a stable, very fine grain size (typically  $< 10 \mu\text{m}$ , or  $400 \mu\text{in.}$ ) (Ref 80). This requirement also usually (but not always) leads to the necessity for a uniform distribution of a fine, second phase to inhibit matrix grain growth. Furthermore, the grain boundaries should be high angle (that is, disordered), equiaxed, mobile, and must resist separation under tensile stresses (Ref 81). To prevent cavitation around the second-phase particles, the strengths of the two phases should be similar at the temperature of deformation (Ref 81). These microstructural characteristics can lead to a flow stress that is highly sensitive to changes in strain rate, which in turn resists the formation of instabilities during tensile deformation.

Even though superplasticity has been observed in many metallic alloy systems, only a relatively small number of them are iron-base. This is because of the difficulty in generating microstructures in these systems with the aforementioned characteristics. As a result, there have been relatively few industrial applications involving the superplastic bulk forming of ferrous alloys. Those iron-base systems in which the microstructural requirements have been met include:

- Hypoeutectoid and eutectoid plain carbon steels (ferrite-carbide two-phase system)
- Hypereutectoid plain carbon steel (ferrite-carbide and austenite-carbide two-phase systems) and white cast iron (ferrite-carbide two-phase system)
- Low-to-medium alloy steels (ferrite-austenite two-phase system)
- Microduplex stainless steels (ferrite-austenite two-phase system)

Of these, only the hypereutectoid steels have been extensively investigated for applications involving superplastic forming.

The development and existence of superplasticity in all of the aforementioned categories of iron-base alloys have been reviewed in detail (Ref 82, 83). This article describes the key characteristics of superplastic behavior in each of these iron-base systems, with emphasis on

hypereutectoid plain carbon steels, which currently have the most industrial potential.

**Hypoeutectoid and Eutectoid Plain Carbon Steels.** Early attempts at making superplastic plain carbon steels were not particularly successful (Ref 82). In these early efforts, extensive heat treatments were used to produce microstructures of fine ferrite grains pinned by spheroidized cementite particles in compositions containing between 0.2 and 1.0% C. Even though the overall grain structure was correct, elongations of only approximately 130% were observed, primarily because the grain boundaries were low-angle dislocation boundaries. The flow stress of materials with low-angle grain boundaries is usually not sensitive to changes in strain rate; therefore, superplasticity was not observed. However, later work showed that thermally cycling such materials across the eutectoid transformation temperature after thermomechanical processing changes the grain boundaries from low angle to high angle; tensile elongations of the order of 1000% have been achieved in thermally cycled, hypoeutectoid plain carbon steels (Ref 80).

**Hypereutectoid Plain Carbon Steels and White Cast Irons.** Hypereutectoid plain carbon steels, also known as ultrahigh-carbon (UHC) steels, will exhibit a microstructure consisting of a continuous network of proeutectoid carbide (at prior-austenite grain boundaries) surrounding pearlite colonies when slowly cooled from a temperature in the single-phase austenite region. This carbide network in turn imparts poor mechanical properties to these steels. However, work conducted in the 1970s showed that, with proper thermomechanical processing, microstructures can be achieved in UHC steels that consist of ultrafine, equiaxed grains of ferrite and a uniform distribution of fine, spherical, discontinuous proeutectoid carbide particles (Ref 84). Such microstructures in UHC steels have led to superplastic behavior; tensile elongations up to 1500% have been reported (Ref 85).

The requisite thermomechanical processing of UHC steels to obtain the desired fine spheroidized microstructure usually involves two steps. In the first step, the UHC ingot or billet is solution heat treated at typically  $1150^\circ\text{C}$

( $2100^\circ\text{F}$ ), followed by hot and warm working during cooling down to  $750^\circ\text{C}$  ( $1380^\circ\text{F}$ ). This step refines the austenite grains, uniformly distributes the proeutectoid carbides at prior-austenite grain and subgrain boundaries, and forms pearlite in the matrix of the prior-austenite grains. The second step incorporates a divorced eutectoid transformation in which the UHC steel is heated to just above the eutectoid transformation temperature and air cooled (with or without accompanying deformation). This step transforms the fine pearlite from step 1 into a fully spheroidized fine structure. The divorced eutectoid transformation is discussed in more detail in Ref 86.

Although not yet fully commercialized, the industrial potential of UHC steels has been thoroughly investigated. One promising application is in the press forging of gears. Figure 47 illustrates a bevel gear that was warm forged from a fine-grain 1.25% C UHC steel in a single operation. An additional advantage of using superplastic UHC steels is that, because of their high carbon content, the carburization step in normal gear production is eliminated. A second example of the superplastic press forming of fine-grain UHC steels is the aft closure for a guided missile, shown in Fig. 48. In this case, a 1.6% C steel casting was liquid atomized, and the resulting fine-grain powders were warm pressed into a billet at  $800^\circ\text{C}$  ( $1470^\circ\text{F}$ ). A third application for superplastically formed fine-grain UHC steels is in the manufacture of die components by superplastic hobbing operations (Ref 87).

The original work on UHC steels demonstrated that, given the proper microstructure, superplasticity could be developed over the composition range of approximately 0.8 to 2.1% C and the temperature range of approximately  $650$  to  $800^\circ\text{C}$  ( $1200$  to  $1470^\circ\text{F}$ ). Therefore, superplastic UHC steels include both austenite-carbide as well as ferrite-carbide two-phase structures. Ultrahigh-carbon steels are generally not susceptible to cavitation, because the ferrite, austenite, and carbide all have approximately the same strength in the intermediate temperature range in which superplasticity occurs.

Furthermore, in the original work, superplasticity in UHC steels was limited to intermediate strain rates (that is, forming rates):  $10^{-5}$

**Fig. 47** Warm precision forging of a 1.25% C ultrahigh-carbon steel billet into a bevel gear. Forging temperature was  $650^\circ\text{C}$  ( $1200^\circ\text{F}$ ).

(a)

(b)

(c)

**Fig. 48** Aft closure, for a guided missile, that was superplastically formed at  $815^\circ\text{C}$  ( $1500^\circ\text{F}$ ) from a 1.6% C ultrahigh-carbon steel. The processing procedure consisted of warm pressing ( $800^\circ\text{C}$ , or  $1470^\circ\text{F}$ ) liquid-atomized powders into a billet and forging the resulting billet into plate. The plate was then superplastically formed to the final shape (a) and (b). (c) Cross section of the part

to  $10^{-3} \text{ s}^{-1}$ . The upper limits on strain rate and temperature are primarily related to the destruction of the fine uniform carbide structure. Commercialization of superplastic UHC steels has in fact been hampered by these somewhat limited strain-rate and temperature ranges. However, work has shown that these ranges could be substantially extended by careful alloying additions of silicon or aluminum (Ref 88). These elements enhance superplasticity in UHC steels because they:

- Increase the eutectoid transformation temperature (increase the stability of ferrite)
- Inhibit carbide coarsening at high temperatures (increase the activity of carbon in ferrite)
- Increase the volume fraction of proeutectoid carbides
- Do not form active sites for cavitation to occur

Ultrahigh-carbon steels containing 3% Si or 1.6% Al have exhibited superplasticity at strain rates to  $10^{-2} \text{ s}^{-1}$  at a temperature of  $800^\circ\text{C}$  ( $1470^\circ\text{F}$ ). Superplasticity has been projected to occur in a UHC 12% Al alloy at strain rates to  $3 \times 10^{-1} \text{ s}^{-1}$  at  $950^\circ\text{C}$  ( $1740^\circ\text{F}$ ); this would make superplastic forming of UHC steels both economical and feasible for many operations.

An additional benefit of adding aluminum or silicon to UHC steels is a low, fairly constant ( $14 \pm 1.5 \text{ MPa}$ , or  $2.00 \pm 0.22 \text{ ksi}$ ) flow stress over the temperature range of  $750$  to  $925^\circ\text{C}$  ( $1380$  to  $1700^\circ\text{F}$ ). This suggests that thin-sheet UHC steels containing the proper amounts of aluminum or silicon can be readily blow formed over a wide temperature range.

**Hypereutectoid White Cast Irons.** Application of rapid solidification processing to UHC steels has also helped to extend the compositional range for superplasticity well into the white cast irons. Such techniques can create very high-carbon-content powders that, upon annealing at intermediate temperatures ( $595$  to  $700^\circ\text{C}$ , or  $1100$  to  $1290^\circ\text{F}$ ), exhibit the requisite fine microstructure (Ref 89). These powders are then readily consolidated into fully dense compacts at temperatures below the subcritical annealing temperature ( $A_1$ ) (Ref 90). White cast irons processed in this manner have been shown to exhibit superplasticity at intermediate temperatures; a maximum tensile elongation of 1410% has been observed in a Fe-3.0C-1.5Cr (Ref 91). The shaded region on the iron-carbon phase diagram shown in Fig. 49 illustrates the range of carbon content and temperature over which superplasticity has been documented in fine-grain UHC steels and cast irons.

**Hypereutectoid Steel Properties.** Because of their carbon content, UHC steels, after superplastic forming, can be heat treated to very high hardness levels (65 to 68 HRC). This can be important in a wide variety of applications, including gears, tool bits, abrasion-resistant surfaces, and military vehicle armor. However, because of their very fine grain size, plain carbon UHC steels also exhibit poor hardenability. This hardenability problem can be alleviated by dilute

alloying additions of hardenability-enhancing elements, such as chromium, manganese, and molybdenum. The dramatic effect of alloying additions on the hardenability of UHC steels is shown in Table 3.

The room-temperature tensile properties of fine-grain UHC steels have been extensively studied (Ref 92). As expected, the properties are very sensitive to heat treatment. Figure 50 compares the tensile properties of UHC steels in two different heat treatment conditions with the properties of other plain carbon and low-alloy structural steels. In addition, if properly heat treated to achieve an extremely fine (optically unresolvable) martensite, fully hardened UHC steels will exhibit a surprisingly high strain to failure in compression. As shown in Fig. 51, a 1.3% C steel that was water quenched from

$770^\circ\text{C}$  ( $1420^\circ\text{F}$ ) (steel A) will exhibit a compression fracture strength of 4.5 GPa (650 ksi) and a strain to failure of 10%. However, austenitizing the same steel at  $1100^\circ\text{C}$  ( $2010^\circ\text{F}$ ) prior to water quenching from  $770^\circ\text{C}$  ( $1420^\circ\text{F}$ ) (steel B) will coarsen the resulting martensite and reduce the compression strain to failure to less than 2%.

Because they contain a high volume fraction of carbide, UHC steels exhibit only moderate impact resistance ( $< 25 \text{ J}$ , or 18 ft.-lbf, Charpy V-notch at  $25^\circ\text{C}$ , or  $80^\circ\text{F}$ ). The impact resistance of fine-grain UHC steels can be enhanced by laminating them to tougher (but weaker) materials. Fine-grain UHC steels can be readily solid-state bonded to themselves or other ferrous materials, partly because of their superplastic nature (Ref 93). The lamination procedure can

**Fig. 49** Iron-carbon phase diagram. The shaded area illustrates the temperature and composition over which ultra-high-carbon steels and white cast irons have been made superplastic.

**Table 3** Hardenability of ultrahigh-carbon (UHC) steels as a function of alloying additions

Material composition	Austenitizing temperature ( $A_1 + 50$ )		Critical brine temperature to achieve 62 HRC, $T_c$		Critical cylinder diameter, $D_c$		M.F.(a)

consist of conventional roll bonding, press bonding, or explosive techniques as long as a good metallurgical bond results. The effect of such lamination on the impact properties of UHC steels is illustrated in Fig. 52. The impact properties of a UHC steel/1020 steel laminated composite are clearly superior to those of either the monolithic UHC steel or the monolithic

1020 low-carbon steel. Most UHC steel-base laminates will also exhibit superplasticity over limited temperature and strain-rate ranges and therefore can be superplastically formed (Ref 94, 95). The room-temperature tensile strength of a UHC steel laminate will of course be reduced relative to that of a monolithic UHC steel by an amount governed by the rule of

mixtures; however, this loss in strength can be partially compensated for by heat treating the laminate to selectively harden the UHC steel component to very high strength levels.

**Low-to-Medium Alloy Steels.** Superplastic studies have been conducted on several alloy steels (Ref 82). Compositions and thermo-mechanical processing procedures are generally chosen to generate fine-grain (1 to 2  $\mu\text{m}$ , or 40 to 80  $\mu\text{in.}$ ) microstructures consisting of roughly equal amounts of ferrite and austenite. These phases will coexist only in a narrow temperature range, but within that range each phase will inhibit the other from growing, and superplasticity will occur. Elongations of 300 to 500% have been achieved in steels containing 1 to 2% Mn and 0.1 to 0.4% C, and elongations of up to 600% have been achieved in Fe-4Ni-3Mo-1-2Ti alloys when tested at temperatures in the dual-phase region. However, the potential of superplastic forming these alloys has not been exploited, because of the narrow temperature range over which superplastic flow occurs and because of the rapid growth that can occur even in the two-phase region at high temperatures.

**Microduplex stainless steels** are so called because their stable microstructure consists of both ferrite and austenite in fine grain size form—approximately 2 to 3  $\mu\text{m}$  (80 to 120 min). They typically contain 18 to 26% Cr and 5 to 8% Ni and can also contain molybdenum, titanium, copper, silicon, manganese, carbon, and diatomic nitrogen. Elongations to failure in these alloys are commonly in excess of 500% at strain rates between  $10^{-3}$  and  $10^{-2} \text{ s}^{-1}$  and at temperatures between 900 and 1000  $^{\circ}\text{C}$  (1650 and 1830  $^{\circ}\text{F}$ ) (Ref 95). Although microduplex stainless steels have found a number of commercial applications in the chemical industry because of their high strength and corrosion resistance, their superplastic forming potential has not been exploited. This is because

microduplex stainless steels are susceptible to cavitation during superplastic flow due to the strength differential between the ferrite and the austenite at these high temperatures (Ref 96).

#### Outlook for Superplastic Ferrous Alloys.

The number of iron-base alloys exhibiting superplasticity is relatively limited. This is primarily because of the difficulty in satisfying all of the microstructural requirements generally required for superplasticity in ferrous materials. Of the alloys identified to date for possible superplastic forming, the hypereutectoid (or UHC) steels show the most promise. These steels can be stretched without cavitation over 1000% at reasonable forming rates and intermediate temperatures. Ultrahigh-carbon steels are heat treatable to high hardnesses, exhibit good room-temperature mechanical properties, and can be readily laminated to other ferrous materials to enhance toughness and impact resistance. Future efforts in the superplastic forming of iron-base alloys will undoubtedly focus on this class of steels.

# Spinning

B.P. Bewlay, General Electric Global Research  
D.U. Furrer, Ladish Company

METAL SPINNING is a term used to describe the forming of metal into seamless, axisymmetric shapes by a combination of rotational motion and force (Ref 1–4). Metal spinning typically involves the forming of axisymmetric components over a rotating mandrel using rigid tools or rollers. There are three types of metal-spinning techniques that are practiced: manual (conventional) spinning (Ref 1, 2), power spinning (Ref 4–11), and tube spinning (Ref 7, 8). The first two of these techniques are described in this article. Tube-spinning technology is described in the articles “Flow Forming” and “Roll Forming of Axially Symmetric Components” in *Metalworking: Bulk Forming*, Vol 14A of *ASM Handbook*, 2005.

Figure 1 shows examples of products from metal spinning. The range of components include:

- Bases, baskets, basins, and bowls
- Bottoms for tanks, hoppers, and kettles
- Canopies, caps, and canisters
- Housings for blowers, fans, filters, and flywheels
- Ladles, nozzles, orifices, and tank outlets
- Pails, pans, and pontoons
- Cones, covers, and cups
- Cylinders and drums
- Funnels and horns
- Domes, hemispheres, and shells
- Rings, spun tubing, and seamless shapes
- Vents, venturis, and fan wheels

The equipment for metal spinning is based on lathe technology, with appropriate modifications for the components that are being formed. Typically, sheet preforms are employed to allow relatively low forming stresses. Metal spinning can be used to cost-effectively produce single or a small number of parts out of expensive materials, such as platinum, or large quantities of components of low-cost materials, such as aluminum reflectors. In this article, the term *pre-form* is used to describe the component both before and during metal spinning; other terms that are sometimes used include *workpiece* and *starting blank*.

In manual spinning, a circular blank of a flat sheet, or preform, is pressed against a rotating mandrel using a rigid tool (Ref 1, 2). The tool is

moved either manually or hydraulically over the mandrel to form the component, as shown in Fig. 2. The forming operation can be performed using several passes.

Manual metal spinning is typically performed at room temperature. However, elevated-temperature metal spinning is performed for

components with thick sections or for alloys with low ductility. Typical shapes that can be formed using manual metal spinning are shown in Fig. 3 and 4; these shapes are difficult to form economically using other techniques. Manual spinning is only economical for low-volume production. Manual metal spinning is

**Fig. 1** Various components produced by metal spinning. Courtesy of Leifeld USA Metal Spinning, Inc.

**Fig. 2** Schematic diagram of the manual metal-spinning process, showing the deformation of a metal disk over a mandrel to form a cone

**Fig. 3** Typical components that can be produced by manual metal spinning. Conical, cylindrical, and dome shapes are shown. Some product examples include bells, tank ends, funnels, caps, aluminum kitchen utensils, and light reflectors.

extensively used for prototypes or for production runs of less than ~1000 pieces, because of the low tooling costs. Larger volumes can usually be produced at lower cost by power spinning or press forming.

Power spinning of metals and alloys is also known as shear spinning (Ref 4–11), because this forming method employs high shear forces. There are two large-volume applications of power spinning: metal cone spinning and metal tube spinning. Power spinning can also be employed to produce hemispheres, provided a preform of the appropriate design is employed. In cone spinning, a flat blank or metal sheet is deformed over a mandrel at high speed.

Almost all ductile metals can be shaped using power spinning (provided they have a minimum ductility corresponding to an elongation of ~2%). Some of the alloys used to make components by metal spinning include:

- 300- and 400-series stainless steels
- Precipitation-hardening stainless steels (17-4PH, 17-7PH)
- Iron-nickel superalloys (A-286)
- Nickel-base superalloys such as Hastelloys (X, C, B, S) and Inconels (600, 625, 718, X-750), N-155, Nimonic 263, and Waspaloy
- Cobalt-base alloys (Haynes 188, Haynes 230)
- Other nonferrous alloys such as aluminum, brass, copper, and platinum

A wide range of shapes can be produced with relatively simple tooling. Power spinning can be used to form large conical parts (up to 3 m, or 10 ft, in diameter) to close tolerances ( $< \pm 0.5$  mm, or 0.020 in.); there is little scrap material, and the forming operation can be completed quickly. The high material utilization is highly desirable, because the preforms for power spinning can be expensive, particularly for aerospace components.

Products that can be produced by metal spinning range from small hardware items made in large quantities (such as metal tumblers and automotive components) to household articles to large components for aerospace applications in low-volume production. Some examples of metal components that are spun include trophies, kettles, kettle drums, cymbals, tank ends, centrifuge parts, pressure bottles, venturis, radar

reflectors, parabolic dishes, wheel discs, and wheel rims.

The use of elevated metal temperatures is sometimes required during metal spinning to reduce the flow stress and increase the ductility of the component, particularly if the machine capacity is insufficient for cold forming the component or if the alloy ductility is too low. Although power spinning can be performed with only one roller, two rollers are generally preferred to balance the radial forces acting on the mandrel and the bearings within the lathe. Power spinning involves large plastic strains and relatively high strain rates, and as a result, significant heat can be generated during forming; the heat is generally dissipated using a coolant/lubricant during power spinning.

The surface finish of spun components is usually of sufficient quality that no additional machining is required after spinning. The surface finish of spun components is typically approximately  $1.5 \mu\text{m}$  (0.06 mil), although finishes as smooth as  $0.5 \mu\text{m}$  (0.02 mil) have been produced by power spinning. Preforms are generally used for cone spinning when the included angle of the component is less than  $35^\circ$  or when the percentage of wall reduction is high, as is described in more detail subsequently. The preforms are typically cold formed in a die, although hot forging or machining, or a combination of both, can also be used.

In this article, manual spinning is described first, and power spinning is described second. For each of these techniques, the process technology, equipment, and tooling is described.

## Manual Spinning of Metallic Components

**General Description.** Manual metal spinning is practiced by pressing a tool against a circular metal preform that is rotated using a lathe-type spinning machine. The tool typically has a work face that is rounded and hardened. Some of the traditional tools are given curious names that describe their shape, such as “sheep’s nose” and “duck’s bill.” The first manual spinning machine was developed in the 1930s. Manual metal spinning involves no significant thinning of the work metal; it is essentially a shaping technique. Metal spinning can be performed with or without a forming mandrel. The sheet preform is usually deformed over a mandrel of a predetermined shape, but simple shapes can be spun without a mandrel. Various mechanical devices and/or levers are typically used to increase the force that can be applied to the preform. Most ductile metals and alloys can be formed using metal spinning. Manual metal spinning is generally performed without heating the workpiece; the preform can also be preheated to increase ductility and/or reduce the flow stress and thereby allow thicker sections to be formed.

Manual metal spinning is used to form cups, cones, flanges, rolled rims, and double-curved surfaces of revolution (such as bells). Typical

shapes that can be formed by manual metal spinning are shown in Fig. 3 and 4; these shapes include components such as light reflectors, tank ends, covers, housings, shields, and components for musical instruments. The maximum practical component diameter is often limited by the size of the available equipment. The upper limit of component thickness increases as preform ductility increases or as flow stress decreases. For example, the manual spinning of aluminum as thick as ~6 mm (0.24 in.) is possible. The practical maximum thickness of low-carbon steel that can be deformed by spinning without mechanical assistance is ~3 mm (0.12 in.).

Manual metal spinning has several advantages and several disadvantages over alternate processes such as press forming or forging (Ref 1, 2). There are three advantages of manual metal spinning. First, the tooling costs and investment in capital equipment are relatively small (typically, at least an order of magnitude less than a typical forging press that can effect the same operation). Second, the setup time is shorter than for forging. Third, the design changes in the workpiece can be made at relatively low cost. However, there are several disadvantages of manual metal spinning. First, highly skilled operators are required, because the uniformity of the formed part depends to a large degree on the skill of the operator. Second, manual metal spinning is usually significantly slower than press forming. Third, the deformation loads available are much lower in manual metal spinning than in press forming. Manual metal spinning and power spinning are generally in competition with pressing and deep drawing.

**Equipment for Manual Spinning—Lathes and Tooling.** A simple tool and sheet preform setup for manual metal spinning is shown in Fig. 5(a). The forming mandrel is mounted on the headstock of a lathe. The circular preform is clamped to the mandrel by the follower. Pressure is applied at the tailstock by means of an anti-friction center and suitable pressure to form the component. The tool rest and pedestal permit the support pin (fulcrum) to be moved to various positions. Metal spinning is performed by manually applying the friction-type spinning tool as the preform is rotated. Figure 5(b) shows a more complex setup for manual metal spinning. In this arrangement, the spinning rollers are mounted in the fork sections of long levers, and the tool support has a series of holes to adjust the tool position. The roller is manipulated by moving two scissorlike handles around the preform/workpiece.

Horizontal metal-spinning lathes that can spin preforms with diameters in the range of ~6 mm to 1.8 m (0.24 in. to 5.9 ft) have been built. For large-diameter parts that may be formed at high speeds, special pit lathes (per the safety requirements) that permit the spinning of blanks as large as ~5 m (16 ft) in diameter have been built. Standard lathes can also be fitted with special tooling for making oval parts. Tooling costs are generally low for manual spinning. However, manual spinning is generally

**Fig. 4** Photograph of conical components that were produced by metal spinning. Courtesy of Leifeld USA Metal Spinning, Inc.

performed using multiple passes, and tool life can be low. Hydraulic lathes were introduced after about 1945 for forming components with either a thicker section or higher-strength alloys. A reliable spinning machine must possess a significant mass in order to ensure stability; the mass provides vibration-free operation when producing components to tight and repeatable tolerances at high speed. The high speeds associated with metal-spinning processes require considerations for all safety aspects of the process.

Mandrel technology plays a very important role in metal spinning. The mandrels are also sometimes referred to as form blocks or spin blocks for manual spinning. The mandrels can be made of seasoned hard-maple wood or metals or combinations of the two. Most hardwood mandrels are constructed by gluing strips of 25 to 50 mm (1.0 to 2.0 in.) thick maple into the main block to create a cross-laminated structure to increase strength. Such mandrels are stronger and more durable than mandrels machined from a solid block. Some wooden mandrels are reinforced with steel at the ends and at small radii, to ensure maintenance of radii in the final part. Minimum inside radii of 1.6 mm (0.06 in.) are possible using mandrels of appropriate construction; corners with radii of smaller than 1.6 mm (0.06 in.) are not desirable. Corners with radii of greater than 3 mm (0.12 in.) are preferred where possible.

Other mandrel materials include steel, cast iron, aluminum, magnesium, and plastic-coated wood. When it is necessary to produce parts to close tolerance, the mandrels are typically made entirely of steel and cast iron. Cored castings of steel or cast iron are preferred in order to reduce the rotating weight. Mandrels must be statically balanced, and, when used at high speed, the mandrels should also be dynamically balanced.

Simple metal-spinning tools can be made by forging carbon or low-alloy tool steels to the desired shape and hardening the working surfaces to a hardness of ~60 HRC. The rollers also need to be polished when surface finish of the final part is important. Typically, the rollers are made of hardened tool steel or aluminum bronze.

#### Process Technology for Manual Spinning.

Manual metal spinning is extensively used for prototypes or for production runs of less than ~1000 pieces, because of the low tooling costs. Larger volumes can usually be produced at lower cost by power spinning or press forming. For large-quantity production, power spinning can generally be conducted at lower cost than manual metal spinning. For example, a stainless steel cover for a food-processing machine (with a shape similar to that shown in the middle of Fig. 3) can be produced economically at the rate of 100 per year using manual metal spinning.

Conical parts (such as the shapes in Fig. 4) are ideally suited for metal spinning because only one tool is required; drawing in dies would require four or five operations. Many such cones can be spun in one operation at a moderate production rate, depending on their included angle. For large-quantity production, power spinning is generally less expensive than manual metal spinning. In cone spinning, the deformation of the metal from the flat blank is performed in accordance with the sine law, as is described in more detail in the section "Mechanics of Cone Spinning" in this article.

The rotational speeds that are best suited to manual metal spinning depend mainly on work metal composition and thickness. For example, a given blank of stainless steel can be spun at a surface speed of 60 m/min (200 surface feet per minute, or sfm). Under otherwise identical conditions, changing to an aluminum blank will permit speeds of 120 to 180 m/min (400 to 600 sfm). Selection of optimal speed depends largely on operator skill. In many metal-spinning operations, speed is changed (usually increased) during the operation by means of a variable-speed drive on the headstock. The dimensional tolerances that can be achieved by manual spinning increase as the diameter of the component decreases. For components up to 300 mm (12 in.) in diameter, tolerances of  $\pm 0.20$  mm (0.008 in.) can be achieved. For larger-diameter components, the tolerances are worse. For example, parts ~4 m (13 ft) in diameter can only be produced to tolerances of approximately  $\pm 1.0$  mm (0.04 in.), but this is machine dependent.

Lubricants generally need to be used in all metal-spinning operations, regardless of the preform composition or shape or the type of metal-spinning tools that are used. Lubricants are typically required both before and during forming. The need for lubrication during spinning depends on the tenacity of the lubricant used and on the rotational speed of the preform. The lubricant must continue to adhere to the rotating preform during spinning. Ordinary cup grease is often used. It can be heated to reduce its viscosity, for ease of application. Other lubricants used for metal spinning include soaps, waxes and talloes, and pigmented drawing compounds; in the selection of the most suitable lubricant, the ease of removal of the lubricant after forming has to be considered.

## Power Spinning

**General Description.** Power spinning of metals and alloys is also known as shear spinning, because in this method metal is deformed using high shear forces (up to 3.5 MN, or 800,000 lbf). There are two broad applications of power spinning: metal cone spinning and metal tube spinning. In cone spinning, the deformation of the metal from the flat blank is performed in accordance with the sine law, as is described subsequently. Almost all ductile metals can be shaped using power spinning (provided they have a minimum ductility of ~2%). Products range from small hardware items made in large quantities (metal tumblers, for example) to large components for aerospace applications in low-volume production. A classic low-production-volume example of power spinning involved the Concorde engine compressor shaft (Ref 4), which was formed by a combination of forging and spinning, because this was more efficient than forging alone.

Metal blanks as large as 6 m (20 ft) in diameter have been successfully formed using power spinning. Conical and curvilinear shapes are most commonly produced from flat (preformed) blanks by power spinning. Plate stock up to 25 mm (1.0 in.) thick can be power spun at room temperature. Blanks as thick as 140 mm (5.5 in.) have been successfully spun at elevated temperature.

**Mechanics of Cone Spinning.** The most common application of power spinning is for conical shapes. In this variant, the metal is volumetrically displaced in the axial direction. The metal deformation occurs in accordance with the sine law, which relates the wall thickness of the starting blank,  $t_1$ , and the wall thickness of the finished workpiece,  $t_2$ , as  $t_2 = t_1 (\sin \alpha)$ , where  $\alpha$  is half the apex angle of the cone (assuming uniform wall thickness in the conical section). The diameter of the finished component is the same as that of the starting blank. When metal spinning is performed in accordance with the so-called sine law (Ref 1, 2, 4), the thickness of the component in the axial direction is the same as the thickness of the starting blank

**Fig. 5** Typical arrangements for manual spinning using a lathe. (a) Simple arrangement with a friction-type spinning tool. (b) More complex setup using levers and a spinning roller

(Fig. 6). The arrangement shown in Fig. 6 is for cone spinning using a single pass.

When spinning metal cones to small angles ( $<35^\circ$  included angle), it is generally easier to use multiple spinning passes with different cone angles for each pass, as illustrated in Fig. 7; typically, the component is annealed or stress relieved between passes. The practice of multiple passes with intermediate anneals permits a high total reduction while maintaining a practical reduction limit of 50 to 75% between process anneals. The reduction between successive annealing operations is determined by the maximum deformation limit for the metal being spun, as is described subsequently.

Deformation limits are shown for a range of alloys in Table 1; the deformation limit is obtained by multiplying the thickness of the starting preform,  $t_1$ , by the maximum reduction factor and then dividing the result by  $t_1$  to obtain the sine of the half-angle required for the conical mandrel.

In power spinning of small-angle cones (as shown in Fig. 7), even when multiple-pass spinning is used, the original blank diameter is retained, and the exact volume of material is used in the final part. At any diameter of either the preform or the completed workpiece, the axial thickness equals the thickness of the

original blank. For example, if a flat plate has a diameter of 190 mm (7.5 in.) and a thickness of 12.5 mm (0.5 in.), the spun preform has the same 12.5 mm (0.5 in.) axial thickness, but the wall thickness is only 6.25 mm (0.25 in.) ( $t_2$  in Fig. 7), thus satisfying the sine law. Similarly, the final workpiece has an axial thickness of 12.5 mm (0.5 in.), but in accordance with the sine law, it has a wall thickness of only 3.1 mm (0.125 in.) ( $t_3$  in Fig. 7).

Deviations from the sine law that can occur are usually expressed in terms of overreduction or underreduction. In overreduction, the final thickness of the workpiece is less than that indicated by the sine law; in underreduction, the thickness is greater. In overreduction, the flange on the cone will lean forward; in underreduction, the flange on the cone will lean backward. If a thin blank is spun with severe underreduction, the flange can also wrinkle.

**Machines for Power Spinning—Lathes and Tooling.** Power spinning is generally performed using special-purpose machines. The significant components of a power-spinning machine are shown schematically in Fig. 8.

Although Fig. 8 illustrates power spinning of a conical shape, similar machines can be used for power spinning of tubes. Figure 9 shows a

horizontal lathe for spinning large-diameter cone and dish-shaped components, and Fig. 10 is a photograph of some remarkably large-diameter ( $\sim 2$  m, or 6.5 ft) cone- and dish-shaped components that were produced by metal spinning. Spinning machines can also be configured to

accommodate several different rollers with quick switchovers.

Machines for power spinning are generally specified by the diameter and length of the largest component that can be spun and the maximum load that can be applied to the work. Metal-spinning machines can be vertical or horizontal. Machines used for spinning large-diameter and large-mass preforms, such as 1.8 m (6 ft) or more in diameter, are usually vertical because they are better suited to handling large components. A broad range of power-spinning machines has been built. The capacity of spinning machines ranges from 455 mm (18 in.) diameter and 380 mm (15 in.) length (maximum component dimensions) to machines capable of spinning workpieces as large as 6 m (20 ft) in diameter and 6 m (20 ft) long. The load on the work can be as great as 3.5 MN (800,000 lbf). Figure 11 shows an automated metal-spinning machine that can be configured for forming cone-shaped components. The lathe, roller, mandrel, and controls work station can be seen.

Machines for power spinning can be automated in a variety of ways. Contemporary metal-spinning machines use template guides that control the shape and accuracy of the workpiece. Most modern machines used for production spinning are at least semiautomatic; that is, they are loaded and unloaded by the operator, but the entire spinning cycle is controlled automatically. Machines can also be equipped with automatic loading and unloading devices for high-volume production. The most recent machines employ computer numerically controlled (CNC)-based techniques, with both playback and CNC controls. In playback mode, the first component is run in manual mode by the operator, typically with joystick control; the program that has been acquired can be modified and optimized for high-speed production.

During power spinning, the tooling is subjected to more severe service conditions than during manual spinning, and as a result, design and manufacture of the tooling must be performed in a more rigorous manner. The tooling that is used for both the rollers and the mandrels is described in the following paragraphs. A typical mandrel profile for cone spinning is

**Fig. 10** Photograph of very large-diameter (~2 m, or 6.5 ft) cone- and dish-shaped components produced by the Leifeld Company. Courtesy of Leifeld USA Metal Spinning, Inc.

shown in Fig. 12. The flange diameter, dimension  $A$ , and the diameter of the nose of the cone, dimension  $B$ , and angle  $\alpha$  can be adjusted as required. The usual practice is to have an integral flange to permit the mandrel to be bolted to the headstock. The radius  $R$  can vary from a minimum of 0.8 mm (0.03 in.) to a round nose. Mandrel wear or failure can be a problem in the power spinning of cones. The mandrels used for production spinning of cones must be hard in order to resist wear, and they must have a high fatigue strength in order to resist the fatigue loading due to the normal eccentric loading during power spinning. Failure is typically caused by spallation of regions from the surface.

The materials used for the mandrels for cone spinning are selected primarily on the basis of the desired mandrel life. The most commonly used

materials are cast irons and tool steels; the actual mandrel material selection depends on the part design, part material, and desired life. For example, gray cast iron can be used for the low-volume (10 to 100 pieces) spinning of soft metals, and alloy cast iron for spinning 100 to 250 pieces; the mandrels can be hardened in areas of high wear. For high-production volumes (250 to 750 pieces), 4150 or 52100 steel hardened to approximately 60 HRC can be used. Tool steels such as O6, A2, D2, or D4 hardened to 60 HRC or slightly higher are more suitable for high-volume production. The surface finish of the mandrels should be at least  $1.5 \mu\text{m}$  (0.06 mil). The mandrel dimensions should be machined so that they are within  $\pm 0.025 \text{ mm}$  (0.0010 in.) of being concentric with each other.

Three types of rollers are used in power spinning; these are shown in Fig. 13. The roller

**Fig. 11** Automated metal-spinning machine for forming cone-shaped components. The lathe, roller, mandrel, and controls work station can be seen. Courtesy of Leifeld USA Metal Spinning, Inc.

**Fig. 12** Typical mandrel used for power spinning of cones. Generally, there are small bosses on the nose and tail for clamping in the tailstock and headstock, respectively. Dimensions given in inches

**Fig. 13** Diagrams of typical forming rollers used for spinning of cones and hemispheres. (a) Full-radius roller. (b) Roller profiled for forming corners. (c) Roller used for reducing the wall thickness. Dimensions given in inches

designs shown in Fig. 13 typically have outside diameters in the range 305 to 510 mm (12 to 20 in.), depending on the type and size of the spinning machine and the part to be formed. Roller widths are usually 50 to 75 mm (2 to 3 in.). The design of the roller employed depends principally on the shape of the component that is to be formed. The full-radius roller design shown in Fig. 13(a) (two axes of symmetry) is generally used to produce curvilinear shapes, and the designs with the radii of curvature shown in Fig. 13(b) and (c) are preferred for the spinning of cones. The design of the rollers, and the alloy used for the rollers, play a critical role in ensuring efficient power spinning.

The roller angle  $\alpha$  shown in Fig. 13(b) and (c) is adjusted to suit the geometry of the component that is being spun (the included angle of the cone has a significant effect on selection of roller design). This roller angle is selected to provide clearance such that the work metal does not contact the faces of the roller where the metal is being deformed (surfaces A and B, shown in Fig. 13(c)). The radius  $R$  should not be less than the final wall thickness.

The roller design illustrated in Fig. 13(b) has been widely used for cone spinning. A typical arrangement for cone spinning, using two opposed rollers, is shown in Fig. 14.

When two rollers are used to spin a part from flat plate, the rollers are positioned at equivalent/symmetric conditions with respect to the preform. However, when metal spinning is performed from a preform, a lead roller is often used, and it is set ahead of the other by 1.5 to 3 mm (0.06 to 0.12 in.). The angle between the axis of rotation of the rollers and the surface of rotation of the workpiece (angle  $\beta$  in Fig. 14) is typically  $\sim 10^\circ$ . The angle between the axis of rotation of the roller and the peripheral face of the roller (angle  $\gamma$  in Fig. 14) can be adjusted for different shapes, and it is also often adjusted during the forming operation; this angle is shown in Fig. 14 as approximately  $30^\circ$ .

Rollers for power spinning are typically made from tool steel or tungsten carbide. A variety of tool steels have been employed, including W2, O6, D2, and D4. The roller material is selected on the basis of the number of parts that are to be formed. D2 and D4 tool steels are preferred for high-production quantities (they should be hardened to 60 to 65 HRC). Tungsten carbide is only used for specialized applications when the high cost can be justified. The rollers should be polished to a maximum surface roughness of  $0.25 \mu\text{m}$  (0.010 mil).

#### Process Technology for Power Spinning.

An important factor in power spinning is the deformation limit, or so-called spinnability, of the metal; the spinnability is the smallest section thickness (or the maximum reduction in thickness) to which a component can be formed by metal spinning without failure of the component. A simple test has been established (Ref 1, 4, 6–8) to determine deformation limit (or spinnability) of a metal, as shown in Fig. 15.

The deformation limit, or spinnability, test is performed by spinning a circular blank over an ellipsoidal mandrel, and spinning is performed so that the outside diameter of the final component is the same as the initial blank. Because the thickness is eventually reduced to zero for the ellipsoidal mandrel, all metals will eventually fail at some thickness,  $t_f$ . The deformation-limit data on a range of materials with different tensile strengths and different formabilities are shown in Fig. 16 and Table 1 (Ref 1, 4).

The deformation limit is defined as:

$$\text{Maximum thickness reduction} = (t_0 - t_f) \times 100/t_0$$

The maximum reduction is plotted against the tensile reduction in area of the material in

**Fig. 14** Schematic diagram showing the relative positions of the preform and two forming rollers used for spinning a cone. One roller can be positioned to follow the second roller, if appropriate for the forming scheme that is being employed.

Fig. 16. It can be seen that if the metal possesses a tensile reduction in area of 50% or greater, the metal can be reduced by power spinning to a thickness of up to 80% in one pass for spinning a cone. The maximum reduction that can be employed to form a hemisphere is less than can be employed for forming a cone. Also, any increase in the material tensile ductility (as described by the reduction in area) above 50% reduction in area does not increase formability or spinnability. For materials with low ductility, if the ductility can be increased by increasing temperature, then the formability can be improved. Process parameters, such as the feed rate and the rotational speed, have a less significant effect on the spinnability.

The best quality for most components is achieved when spinning at high speeds. The minimum surface speed considered to be

**Fig. 15** Schematic diagram of the spinnability test. The thickness of the test coupon is reduced as the roller is advanced; the reduction in thickness at the point of fracture is taken as the maximum spinning reduction per pass. Source: Ref 6

**Fig. 16** Maximum spinning reduction per pass as a function of tensile fracture strain for materials of a range of tensile strengths. For materials with tensile ductilities of greater than 50%, there is no further increase in the spinnability. Source: Ref 1, 4

practical for metal spinning is approximately 120 m/min (400 sfm), and this is only used for spinning small-diameter workpieces. Surface speeds of 300 to 600 m/min (1000 to 2000 sfm) are typically used; this speed range is suitable for a range of metal compositions, preform shapes, and process conditions (such as reduction per pass, roller design, roller position, and forming temperature).

Most cone-spinning operations are performed at linear feed rates of 0.25 to 2 mm/rev (0.010 to 0.08 in./rev); for typical spinning machines, this equates to linear feed rates in the range 38 to 380 mm/min (1.5 to 15 in./min) (feed rates are usually measured in millimeters per minute). Most machines used in cone spinning are equipped with devices that continuously change the rate of feed with the diameter on which the rollers are working.

The feed rate controls the workpiece finish and the material properties and the fit of the workpiece to the mandrel. With all other factors constant, a decrease in the feed rate will improve surface finish. An increase in feed rate will make the workpiece fit tighter on the mandrel, and the finish of the workpiece will become coarser. The use of preforms can influence surface finish and is common in cone spinning when the included angle of the cone is less than 35° or when the percentage of wall reduction is high. Preforms are usually prepared by cold forming in a die, although hot forging or machining or a combination of both can be used.

The surface finish of a spun component is usually of sufficient quality that no additional machining is required after spinning. The surface finish of spun components can typically be approximately 1.5  $\mu\text{m}$  (0.06 mil), although surface finishes as smooth as 0.5  $\mu\text{m}$  (0.02 mil) have been produced by power spinning, when using appropriate tooling and surface finish of the tooling.

A lubricant is almost always used during power spinning. The fluid used serves as both a lubricant and a coolant. A water-based coolant, such as an emulsion of soluble oil in water, is most commonly used, and in large quantities because of the large amount of heat generated. When spinning aluminum, stainless steel, or titanium, the workpieces or mandrels or both are sometimes coated with the lubricant before spinning. An increase in the forming temperature can lead to a reduction in the flow stress and an increase in the ductility of the preform; this is sometimes required if the load capacity of the spinning machine is not sufficient for cold forming the preform or if the room-temperature ductility of the work metal is too low. When operating at elevated temperatures, great diligence must be exercised in the selection and use of an appropriate lubricant.

**Power Spinning of Hemispheres.** Spinning of hemispheres is more complicated than spinning of cones. However, in order to spin hemispheres, preforms of specially designed geometries can be used to adjust the percentage of reduction as a function of radial position, as is

described in the following section. This approach has enabled power spinning to be applied to the forming of hemispheres, ellipses, ogives, and almost any curvilinear surface of revolution. However, the design of the preform for curvilinear shapes is more complicated than that for conical shapes. For the case of spinning of conical shapes, it is possible to determine an axial thickness of the spun part that corresponds to the thickness of the blank (Fig. 6, 7). However, the same relationship does not exist for a curvilinear surface; this problem is illustrated in Fig. 17. In the path from the pole to the equator of a hemisphere, the axial thickness of the metal on a hemisphere changes from stock thickness at the pole to infinity (the inverse of  $\sin 0^\circ$ ) at the equator (the wall thickness, in the normal direction, goes to zero). The blank thickness must therefore be back-tapered to compensate for the change in thickness that takes place during spinning of hemispheres. Figure 17 shows a preform for a ~1.5 m (5 ft) diameter hemisphere; the machined taper started at 3.8 mm (0.15 in.) in thickness in the center of the preform and ended at a thickness of 7.5 mm (0.30 in.) in thickness at the circle where the 30° radial line of the sphere was projected to the blank. At the corresponding 45° line, the blank thickness was 5.4 mm (0.21 in.), and the final part thickness was 0.71 times the original thickness. For the region of the hemisphere below the 30° line, the reduction of the preform was greater than permissible for spinning aluminum alloy 6061 (according to the previous description), and the forming operation was performed as if spinning a cylinder; the preform for this region had a flange with a thickness proportional to the designed percentage of reduction.

As an example, a suitable preform for spinning a hemisphere was designed by first finding in Table 1 the maximum allowable reduction for the material that was used in order to obtain the minimum part thickness associated with the deformation limit and minimum angle of the cone. A beginning stock thickness was selected that, with the maximum allowable reduction, gave the thickness desired in the final hemisphere sphere. The ratio of finished stock thickness to original stock thickness was then taken as the sine of an angle, which was the angle of the surface at the latitude at which forming was started. Beyond this point, the reduction required to make the hemisphere was greater than is permissible for the 6061 aluminum alloy. At 45° from the pole, final part thickness was 0.71 times the original thickness. Forming started at the circle corresponding to the latitude associated with the forming limit (the point where the maximum permissible reduction has taken place). In a cross-sectional view, the circles resulting from the aforementioned approach become points, and the thickness of the stock at these points can be determined. The correct roller locus can be programmed with state-of-the-art CNC-based techniques.

The following example describes forming a 1.5 m (5 ft) diameter hemisphere by power

spinning. Large hemispheres (Fig. 17) have been power spun from a solution-treated aluminum alloy 6061 using the following calculations. From Table 1 it was determined that a 50% reduction could be used with this alloy. Preliminary calculations for the thickness of the starting preform indicated a thickness of 7.6 mm (0.30 in.) was required (preform thickness = final wall thickness/maximum reduction = 3.8 mm/2).

In calculating the blank thickness profile for various points on the sphere, it was found that at the pole, or 90° point, the thickness had to be reduced to 3.8 mm (0.15 in.) and that a linear reduction was required out to a point directly above the 30° tangency on the hemisphere, where the thickness of the starting blank had to be 7.6 mm (0.30 in.). Beyond this point, a flange was incorporated; the preform thickness was increased in the region by 30% to allow for this flange, and the initial blank thickness was established at 9.9 mm (0.39 in.). Final spinning was accomplished in one pass of the rollers.

The type of procedure described in the previous example has also been successfully used to form both hemispheres and ellipses with diameters in the range of 150 mm to 1.8 m (6 in. to 6 ft). Hemispheres from the following alloys have also been formed: 17-7PH and type 410 stainless steels, alloy steels such as 4130 and 4140, and from aluminum alloys 5086, 2014, 2024, and 6061.

**Effects of Power Spinning on Component Properties.** Power spinning is a severe cold working operation, and it therefore can have a very significant effect on the mechanical properties of the component. Typically, well-defined flow patterns are generated in the grain structure by power spinning. In many applications, the increase in strength caused by spinning is highly desirable, because it eliminates the need for subsequent heat treating. In those applications where the change in mechanical properties is not desired, the component must be annealed after

**Fig. 17** Schematic diagram showing an example of a forming scheme used to spin a large-diameter hemisphere from a preformed blank metal sheet, such as aluminum alloy 6061. The preform is tapered to allow spinning of a hemisphere with a uniform wall thickness. Dimensions given in inches

metal spinning. The effect of power spinning on mechanical properties, such as fatigue performance and creep resistance, is similar to that of other cold working operations.

## Conclusions

This article has described two forming techniques, manual spinning and power spinning, for forming seamless metal components. The equipment for both of these two spinning techniques is based on lathe technology, with appropriate modifications for the components that are being formed. A wide range of components can be produced using these two metal-spinning techniques with relatively simple tooling. Metal spinning is very competitive with other forming processes, such as pressing and deep drawing; it is a highly flexible forming technique.

Metal spinning can be operated economically to produce complicated parts for single applications, low-volume production, and mass production. Manual-metal-spinning and power-spinning processes are very flexible and lend themselves to broad automation. Machine design changes, innovations in control systems, and process developments have led to improvements in all aspects of metal-spinning technology since the 1980s. Manual spinning is generally suitable for low-volume production of components.

This article has described process technology, equipment, and tooling for both manual spinning

and power spinning. Power spinning can be used to form large parts (up to 6 m, or 20 ft, in diameter); there is little scrap material, and the forming operation can be completed quickly. A wide range of shapes can be produced with relatively simple tooling. Power spinning is particularly suited to cones and hemispheres. Other components that can be produced by metal spinning range from small hardware items made in large quantities (such as metal tumblers and automotive components) to large components for high-performance aerospace applications in low-volume production (such as rocket engine casings and missile nose cones).

Other examples of metal components that are spun include trophies, kettles, kettle drums, cymbals, tank ends, centrifuge parts, pressure bottles, venturis, radar reflectors, parabolic dishes, wheel discs, and wheel rims. For these types of complex geometries, manual-metal-spinning and power-spinning techniques are generally preferred over pressing and deep drawing; the advantages of spinning include flexible production, relatively low tooling costs, and short setup times.

# Rubber-Pad Forming and Hydroforming

**RUBBER-PAD FORMING**, also known as flexible-die forming, employs a rubber pad or a flexible diaphragm as one tool half, requiring only one solid tool half to form a part to final shape. The solid tool half is usually similar to the punch in a conventional die, but it can be the die cavity. The rubber acts somewhat like hydraulic fluid in exerting nearly equal pressure on all workpiece surfaces as it is pressed around the form block.

Rubber-pad forming is designed to be used on moderately shallow, recessed parts having simple flanges and relatively simple configurations. Form block height is usually less than 100 mm (4 in.). The production rates are relatively high, with cycle times averaging 1 min or less.

The advantages of the rubber-pad forming processes compared to conventional forming processes are:

- Only a single rigid tool half is required to form a part.
- One rubber pad or diaphragm takes the place of many different die shapes, returning to its original shape when the pressure is released.
- Tools can be made of low-cost, easy-to-machine materials due to the hydrostatic pressure exerted on the tools.
- The forming radius decreases progressively during the forming stroke, unlike the fixed radius on conventional dies.
- Thinning of the work metal, as occurs in conventional deep drawing, is reduced considerably.
- Different metals and thicknesses can be formed in the same tool.
- Parts with excellent surface finish can be formed, because no tool marks are created.
- Set-up time is considerably shorter, because no lining-up of tools is necessary.

The disadvantages are:

- The pad or diaphragm has a limited lifetime that depends on the severity of the forming in combination with the pressure level.
- Lack of sufficient forming pressure results in parts with less sharpness or with wrinkles, which may require subsequent hand work.
- The production rate is relatively slow, making the process suitable primarily for prototype and low-volume production work.

**Equipment.** The hydraulic presses used in most flexible-die forming are similar to those described in the article “Presses and Auxiliary

Equipment for Forming of Sheet Metal” in this Volume. Some processes use special machines, which are described in this article in the discussions of the specific processes. In most applications, only one solid tool half is specially made. The tool half can be made of epoxy resin, zinc alloys, hardwood, or other inexpensive material, as well as aluminum, cast iron, or steel.

Equipment is available with cycling rates as high as 1500 per hour. Some flexible-die forming methods have been applied to high-volume production, such as the forming of deeply recessed taillight reflectors for automobiles, and the deep drawing of toaster shells (example 3).

The application of rubber pads in press-brake dies is discussed in the article “Press-Brake Forming” in this Volume. In the past, flexible-die forming methods were designated by specific processes: Guerin process, Verson-Wheelon process, trapped-rubber process, Marform process, Hydroform process, SAAB process, and Demarest process. Modern technology has reduced this list, categorizing the methods into three basic groups: rubber pad, fluid cell, and fluid forming. Detailed applications of these rubber-die forming processes to specific metals are available in the articles “Forming of Stainless Steel,” “Forming of Aluminum Alloys,” “Forming of Copper and Copper Alloys,” and “Forming of Titanium and Titanium Alloys” in this Volume.

## Rubber-Pad Forming

The Guerin process is synonymous with the term *rubber-pad forming*. An improvement over the Guerin process is the Marform process, which features the addition of a blankholder and die cushion to make this process suitable for deeper draws and to alleviate the wrinkling problems common to the Guerin process. Another variation of the Guerin process is the trapped-rubber process, in which the forming force is provided by a hammer instead of a hydraulic press. Like the Marform process, the trapped-rubber process can be used for deeper draws and results in less scrap due to wrinkling than the basic Guerin process. The design and construction of the ASEA Quintus rubber-pad presses are further refinements of the Guerin and Marform processes.

## Guerin Process

The Guerin process is the oldest and most basic of the production rubber-pad forming processes. Its advantages are simplicity of equipment, adaptation to small-lot production, and ease of changeover.

Some metals that are commonly formed by the Guerin process are listed in Table 1. Titanium can be formed only if the workpiece and the form block are both heated. The resulting deterioration of the rubber pad often makes the process too costly, as compared to forming by conventional dies.

**Presses.** For maximum forming capability, the force capacity of the press and the area of the rubber pad must be suitable for the operation under consideration. The rubber pad is generally approximately the same size as the press ram, but it can be smaller (example 2).

**Tools.** The principal tools are the rubber pad and the form block, or punch (Fig. 1). The rubber pad is relatively soft (approximately Durometer A 60 to 75) and is usually three times as deep as the part to be formed. The pad can consist of a solid block of rubber, or of laminated slabs cemented together and held in a retainer, as shown in Fig. 1. The slabs can also be held loose in a flanged retainer. The retainer is generally made of steel or cast iron, and it is approximately 25 mm (1 in.) deeper than the rubber pad. It is

**Table 1 Metals commonly formed by the Guerin process**

Metal	Maximum thickness(a)

(a) Typical; varies with type of equipment and part design. (b) Up to 2.0 mm (0.078 in.) when compression dams are used (see the section “Accessory Equipment” and Fig. 2 in this article). (c) Only very mild forming. (d) When heated to 315 °C (600 °F)

also strong enough to withstand the forming pressures generated (up to 140 MPa, or 20 ksi, in some applications, although an upper limit of 14 MPa, or 2 ksi, is more common).

The minimum pad thickness is 1/3 times the height of the form block, as shown in Fig. 1. Pad thicknesses generally vary from 150 to 300 mm (6 to 12 in.), and the most commonly used thickness is 200 to 230 mm (8 or 9 in.).

Form blocks are made of wood, plastic, masonite, richlite, cast iron, steel, or alloys of aluminum, magnesium, zinc, kirkcote, or bismuth. The softer materials are used in making prototypes or experimental models or in small production runs. The life of a wood, plastic, or soft-metal form block can be extended by facing it with steel. Form blocks are fitted with locating pins to hold the blanks in position while they are being formed.

The form block is placed on a platen, or pressing block (Fig. 1), which fits closely into the rubber-pad retainer to avoid extrusion of the rubber during the forming process. Several form blocks are often positioned on one platen so that several parts can be formed simultaneously with one stroke of the press. Two or three platens can be used with each press; they can be slid or rotated from under the press ram for loading and unloading.

**Cavity Tools.** With the high pressure attainable on the new hydropresses, more complex parts are able to be formed. The use of traps and dams in conjunction with cavity dies makes it possible to form parts that could only be hammer formed in the past. These parts are often formed in stages, with one or two anneals in between forming steps. When doing short-production or spare work, cavity dies can offer large cost reductions over other conventional processes.

**Accessory equipment** includes draw clips, cover plates, wiping plates, forming rings and forming bars, and dams and wedge blocks. These are used to increase the pressure on the work piece in specific locations and to aid in the forming of difficult shapes.

Draw clips are fastened to the edge of a blank to equalize the drawing force on a flange and to keep it from wrinkling. Wiping plates, usually hinged to the pressing block, mechanically transfer the pressure of the rubber pad to

hard-to-form flanges. Forming rings and forming bars work in the same way, except that they encircle the part and therefore are not hinged. Dams are shaped and positioned so that with the sidewall of the form block they form a trap. The dam has a face sloping toward this trap so that rubber is cammed against the sidewall as the rubber pad moves down, thus increasing the pressure in that area. Wedge blocks use the same kind of camming action to apply mechanical pressure to the side of a workpiece. Examples 1 and 4 in this article illustrate the use of dams. Cover plates are used to hold blanks flat during forming or to protect previously formed areas from distortion.

**Procedure.** The rubber-pad retainer is fixed to the upper ram of the press, and the platen, containing the form block, is placed on the bed of the press. A blank is placed on the form block and is held in position by two or more locating pins. The pins must be rigidly mounted in the form block so that the rubber will not drive them down into the pinhole or push them out of position; and they must be no higher than necessary to hold the blank, or they will puncture the rubber pad. In some applications, nests can be used to locate the blank during forming.

As the ram descends, the rubber presses the blank around the form block, thus forming the workpiece. The rubber-pad retainer fits closely around the platen, forming an enclosure that traps the rubber as pressure is applied. The pressure produced in the Guerin process is ordinarily between 6.9 and 48 MPa (1 and 7 ksi). The pressure can be increased by reducing the size of the platen. Pressures as high as 140 MPa (20 ksi) have been developed through the use of small platens in high-capacity presses (see example 1).

The pressure is not a function of the number of parts being formed but of the platen area. To obtain maximum production with each stroke of the press, therefore, as many form blocks as possible are mounted on a single platen. The depth of the finished parts formed by this process seldom exceeds 38 mm (1 1/2 in.). However, deeper parts can be formed by using a press with a high force capacity and a rubber pad with a small surface area. In one application, such a setup produced 140 MPa (20 ksi) of pressure and was able to form a flange 70 mm (2 3/4 in.) deep.

Straight flanges can be easily bent by the Guerin process if they are wide enough to develop adequate forming force. If the flanges are not wide enough, accessory tools must be used.

Minimum widths for flanges of stainless steel and aluminum alloys that can be bent by rubber-pad forming are listed in Table 2. Angles on flanges in soft metal can generally be held to a maximum variation of  $\pm 1^\circ$ . In hard metals, such as half-hard stainless steels, which have more springback than annealed stainless steels, a  $\pm 5^\circ$  tolerance can be met only with special care. An envelope (all-around) tolerance of  $\pm 0.38$  mm ( $\pm 0.015$  in.) is possible on the contour of soft-metal pieces, but on hard metal, the tolerance must be increased to  $\pm 0.51$  mm ( $\pm 0.020$  in.).

Stretch flanges and shrink flanges can be formed around curves and holes if the deformation is slight to moderate. If forming is severe, auxiliary tools must be used to support the work and to prevent wrinkling.

**Shallow Drawing.** Cover plates are often used to hold webs flat while flanges are being formed. In the following example, a pressure of 140 MPa (20 ksi) was used to form a part so well that only minimal hand reworking was required. To obtain the 140 MPa (20 ksi) pressure, a rubber pad 508 mm (20 in.) in diameter (surface area:  $\sim 0.19$  m<sup>2</sup>, or 300 in.<sup>2</sup>) was mounted in a 27 MN (3000 tonf) hydraulic press. The bed size of the press was 1520 mm (60 in.) front-to-back and 1570 mm (62 in.) left-to-right. Stroke length was 457 mm (18 in.), and shut height was 1270 mm (50 in.). The press had a turntable that held two form blocks; therefore, one block could be unloaded and loaded while the other was under the press ram. The rubber pad was 203 mm (8 in.) thick and made in two pieces. One piece was 178 mm (7 in.) thick and had a hardness of Durometer A 80 to 85. The second piece, which was replaceable, was 25 mm (1 in.) thick and had a hardness of Durometer A 70 to 75.

**Example 1: Shallow Drawing of a Fuselage Tail Cap by the Guerin Process.** The fuselage tail cap shown in Fig. 2 was rubber-pad formed at 140 MPa (20 ksi) using the 27 MN (3000 tonf) hydraulic press and the 508 mm (20 in.) diameter pad described previously. The cap was

(a) Using minimum permissible bend radius; a larger bend radius requires a wider flange. (b) t, sheet thickness

Fig. 2 Fuselage tail cap that was formed by the Guerin process in a high-pressure setup. Dimensions given in inches

originally made by spinning, but at a rate of only one piece per hour. Changing to high-pressure rubber-pad forming by the Guerin process increased the production rate to 12 pieces per hour.

A blank of aluminum alloy 2014-O, 0.81 mm (0.032 in.) thick, was solution heat treated to the W temper and was lubricated with heavy-duty floor wax. The part was formed before age hardening was complete. A compression dam surrounded the form block (Fig. 2) and was used to concentrate pressure on the flange.

**Matched Laminations.** In the following example, accurately matched laminations were made by forming one over the other on a form block by the Guerin process.

**Example 2: Forming of a Two-Piece Cockpit Rail on a Single Form Block.** By using a rubber pad instead of a conventional die, it was possible to form the two mating parts of a cockpit rail section on a single form block. One of the two parts is shown in Fig. 3. The second part was formed over the first after it had been formed.

A fully developed blank, 2.54 mm (0.100 in.) thick, was cut from aluminum alloy 2014-O and solution heat treated. Forming was done by the Guerin process with a minimum pressure of 52 MPa (7.5 ksi). No lubricant was used. The form block (Fig. 3) was made of masonite and was plastic faced. The production rate was 20 pieces per hour.

**Blanking.** With the Guerin process, rubber pads can be used for blanking and piercing as well as for forming. Rubber pads produce better edges on the workpiece than band sawing, and almost as good as those made by routing. An edge radius up to the thickness of the metal can be produced on some heavy-gage metals. The rubber-pad method can blank aluminum alloy 2024-O up to 0.81 mm (0.032 in.) thick and, for some shapes, up to 1.0 mm (0.040 in.) thick. The minimum hole diameter or width of cutout is 50 mm (2 in.). A minimum of 38 mm (1½ in.) trim is needed for external cuts.

The form block has a sharp cutting edge where the blank is to be sheared. In hard-metal blocks, this edge can be cut into the form block, as shown in Fig. 4(a) and (b). Form blocks of soft metal, plastic, or wood need a steel shear plate for the cutting edge (Fig. 4c); the shearing edge should be undercut 3 to 6°.

The trim metal beyond the line of shear must be clamped firmly so that the work metal will

**Fig. 3** Cockpit rail section that was formed on a single form block by the Guerin process. Dimensions given in inches

break over the sharp edge instead of forming around it. This clamping is done by a lock ring (Fig. 4a), a grip plate (Fig. 4b), or a raised extension of the form block (Fig. 4c).

These clamping devices also localize pressure at or near the cutting line. A rounded edge on the finished blank can be produced by locating the lock ring or grip plate a small distance from the shear edge (Fig. 4a and b). The metal droops in the unsupported area and forms around the sharp corner before it shears. The result is a smooth, rounded edge.

**Drawing of shallow parts** is often done by a modification of the Guerin process in which the contour is recessed (for example, a die cavity) into the form block rather than being raised on it. The blank is securely clamped between the rubber pad and the surface around the recess before forming begins.

Clamping the work metal before drawing and the amount of pressure used are both important for successful drawing. The work metal must be securely clamped to prevent it from flowing irregularly and subsequently forming wrinkles, but not so tightly that the metal cannot flow at all, which will cause thinning, or even tearing, of the work metal. To avoid this, either the edges can be lubricated or a protecting block with an undercut slot to accommodate the flange (Fig. 5) can be placed over the edges of the workpiece. The width of the block and undercut must provide the correct balance between clamping force and drawing force. The undercut should be 0.08 to 0.15 mm (0.003 to 0.006 in.) higher than the thickness of the work metal.

### Marform Process

The Marform process was developed to apply the inexpensive tooling of the Guerin and Verson-Wheelon processes (see the section "Verson-Wheelon Process" in this article) to the

**Fig. 4** Three techniques for blanking by the Guerin process categorized by clamping method. (a) Lock ring. (b) Grip plate. (c) Raised extension of the form block

deep drawing and forming of wrinkle-free shrink flanges. A blankholder plate and a hydraulic cylinder with a pressure-regulating valve are used with a thick rubber pad and a form block similar to those used in the Guerin process. The blank is gripped between the blankholder and the rubber pad. The pressure-regulating valve controls the pressure applied to the blank while it is being drawn over the form block.

While forming a soft aluminum alloy blank, the diameter can usually be reduced 57%, and reductions as high as 72% have been obtained. A shell depth equal to the shell diameter is normal when the minimum stock thickness is 1% of the cup diameter. Depths up to three times shell diameter have been reached with multiple-operation forming. The minimum cup diameter is 38 mm (1½ in.).

Foil as thin as 0.038 mm (0.0015 in.) can be formed by placing the blank between two aluminum blanks approximately 0.76 mm (0.030 in.) thick and forming the three pieces as a unit. The inner and outer shells are discarded.

**Presses.** The Marform process is best suited to a single-action hydraulic press in which pressure and speed of operation can be varied and controlled. A Marform unit comes as a package that can be installed in a hydraulic press having ample stroke length and shut height. However, a press that incorporates a hydraulic cushion system into its bed has been designed specifically for Marforming.

The rubber pressures used depend on the force capacity of the press and the surface area of the rubber pad. Recent installations range from 34 to 69 MPa (5 to 10 ksi).

**Tools.** The rubber pad used in Marforming is similar to that used in the Guerin process. It is normally 1½ to 2 times as thick as the total depth of the part, including trim allowance. The rubber pad can be protected from scoring by the use of a throw sheet, which is either cemented to the pad or thrown over the blank.

Well-polished steel form blocks are used for long runs and deep draws. Aluminum alloy form blocks must be hard coated to prevent galling for draws deeper than 38 mm (1½ in.). Masonite form blocks can be used if they can withstand the abuse and wear of forming a particular part in a given quantity. When a cast shape is more economical, aluminum or zinc alloy form blocks can be used.

**Fig. 5** Use of a protecting block to prevent work metal irregularities in shallow drawing by the Guerin process

Blankholder plates are usually made of low-carbon steel. The contact surface is ground flat and polished to avoid scratching of the blank. Clearance between the form block and the mating hole in the blankholder is 0.75 to 1.5 mm (0.030 to 0.060 in.) per side. The edge should have a 1.6 mm ( $1/16$  in.) radius.

A radius plate is necessary when the machine pressure is insufficient for forming the flange radius within tolerance. The part is drawn first without the plate, then redrawn using the plate to form the exact radius. The radius plate is usually 13 mm ( $1/2$  in.) thick and 25 mm (1 in.) wider than the workpiece. A sealing ring is used to prevent the rubber pad from extruding out of the container.

**Procedure.** The blank rests on the blankholder plate above the form block. The rods supporting the seal ring and blankholder plate (Fig. 6) are supported on a variable-pressure hydraulic cushion. As the press ram is lowered, the blank is clamped between the rubber pad and the blankholder before forming begins. As the rubber pad continues to descend, the blank is drawn over the form block while the pressure control valve in the hydraulic cushion releases fluid at a controlled rate. The pressure in the hydraulic cushion must be adjusted to prevent wrinkles from forming in the flange but to permit the blank to be drawn into a smooth shell. The part is stripped from the form block by the blankholder. The following example describes an application of the process.

**Example 3: Deep Drawing of Toaster Shells by the Marform Process.** The toaster shell shown in Fig. 7 was deep drawn in large quantities (80,000 pieces) from 0.76 mm (0.030 in.) thick deep-drawing-quality 1010 steel. The blanks were lubricated by brushing with a soap compound. Available pressure was 41 MPa (6 ksi). The depth of the trimmed shell was 127 mm (5 in.). The reduction time per piece was 22 s.

### Drop Hammer Forming with Trapped Rubber

A process similar to the Guerin process, for forming shallow workpieces, is a trapped-rubber process, which uses a drop hammer in place of the hydraulic press; the primary differences are the faster forming speed and the impact force of

Fig. 6 Tooling and setup for rubber-pad forming by the Marform process

the hammer. The use of rubber pads in drop hammer forming is illustrated in the article "Drop Hammer Forming" in this Volume.

Figure 8 shows the effects of forming flanges on aluminum alloys 5052-O and 2024-O by the drop hammer (trapped-rubber) and Guerin processes. When flanges deeper than 32 mm ( $1\frac{1}{4}$  in.) are made by the Guerin process, stretch flanges can tear and shrink flanges can wrinkle. However, when the drop hammer process is used, fewer deformities occur (Fig. 8).

### ASEA Quintus Rubber-Pad Press

ASEA presses, generally designed with force capacities of 50 to 500 MN (5600 to 56,000 tonf), are constructed of wire-wound frames and have separate guiding columns (Fig. 9). By winding the press frames with prestressed wire, only compressional stresses are present in the large castings or forgings of the yokes and columns, even when subjected to maximum forming pressure. Therefore, when the press is loaded, the frame remains in slight compression, and the major structural components never operate in the tensile mode.

The press is equipped with a forged-steel rubber-pad retainer that has a replaceable insert to allow for forming at even higher pressures. Although the maximum tool height is sacrificed by using these high-pressure inserts, cutting the

Fig. 7 Toaster shell that was deep drawn by the Marform process. Dimensions given in inches

Fig. 8 Effect of impact in forming stretch and shrink flanges by the drop hammer (or trapped-rubber) and Guerin processes. Dimensions given in inches

work area in half doubles the maximum forming pressure of the press when needed.

Standard table sizes range from 0.7 by 1.0 m (28 by 39 in.) to 2 by 3 m (79 by 118 in.). These presses provide forming pressures to 100 MPa (15 ksi). Hard and brittle materials such as titanium, along with the die, can be heated outside the press by an infrared heater; blanks can also be heated by conduction from the table through the heat transferred through the die (Fig. 10).

### Fluid-Cell Forming

Initially developed as the Verson-Wheelon process, the fluid-cell process uses a fluid cell (a flexible bladder) backed up by hydraulic fluid to exert a uniform pressure directly on the form block positioned on the press table. This process can be classified in terms of the presses used (Verson-Wheelon and ASEA Quintus) as well as

Fig. 9 Schematic of ASEA Quintus rubber-pad hydraulic press with wire-wound frame

Fig. 10 Schematic of ASEA Quintus rubber-pad press with provision for heating hard and brittle materials using infrared heater or heating elements contained in feed table

a specialized method (Demarest process) for producing cylindrical and conical parts. The Verson-Wheelon press has cylindrical press housings of laminated, prestressed steel that serve as pressure chambers. The ASEA Quintus press has a forged steel cylinder that is wound with high-strength steel wire to create a pre-stressed press frame with extremely good fatigue properties.

Fluid-cell forming can be used for recessed parts that are beyond the capabilities of rubber-pad forming, for all flange configurations (including C-shaped flanges), and for complex parts with reentrant features and intricate joggles. Maximum form block height is 425 mm (16.7 in.), and typical cycle time is 1 to 2 min.

### Verson-Wheelon Process

The Verson-Wheelon process was developed from the Guerin process. It uses higher pressure and is primarily designed for forming shallow parts, using a rubber pad as either the die or punch. A flexible hydraulic fluid cell forces an auxiliary rubber pad to follow the contour of the form block and to exert a nearly uniform pressure at all points.

The distribution of pressure on the sides of the form block permits the forming of wider flanges than with the Guerin process. In addition, shrink flanges, joggles, and beads and ribs in flanges and web surfaces can be formed in one operation to rather sharp detail in aluminum, low-carbon steel, stainless steel, heat-resistant alloys, and titanium.

**Presses.** The Verson-Wheelon press has a horizontal cylindrical steel housing, the roof of which contains a hydraulic fluid cell (Fig. 11). Fluid-cell bladders can be of neoprene or polyurethane composition. Hydraulic fluid is pumped into the cell, causing it to inflate or expand. The expansion creates the force needed to flow the rubber of the work pad downward, over and around the form block and the metal to be formed.

Below the chamber containing the rubber pad and the hydraulic fluid cell is a passage, extending the length of the press, that is wide and high enough to accommodate a sliding table containing form blocks. At each end of the passage is a sliding table that is moved into position for forming.

The rubber pad used in the Verson-Wheelon process has a hardness of approximately Durometer A 35. It is usually protected from sharp corners on the form block and blank by a throw sheet or work pad that is harder and tougher than the pad itself. The throw sheet is much less costly to replace than the rubber pad below the fluid cell.

Verson-Wheelon presses are available with forming pressures ranging from 35 to 140 MPa (5 to 20 ksi) and force capacities of 22 to 730 MN (2500 to 82,000 tonf). Sliding tables range in size from 508 by 1270 mm (20 by 50 in.) to 1270 by 4170 mm (50 by 164 in.). The

larger machine can form parts having flange widths to 238 mm (9<sup>3</sup>/<sub>8</sub> in.).

Heating elements can be used with the sliding tables for producing parts made of magnesium. The maximum temperature is 315 °C (600 °F), and special heat-resistant throw pads are used to protect the hydraulic fluid cell.

**Tools.** The form blocks for the Verson-Wheelon process are made in much the same way as those for the Guerin process. Compression dams or deflector bars can be used to direct pressure into local areas for forming shrink flanges or return bends, as described in example 4.

Aluminum alloy or zinc alloy form blocks are recommended. Because of the high pressures, masonite or wood form blocks may break down from repeated use. More than one form block can be used at a time; the quantity depends on the size and shape of the form block.

Damage to the rubber pad can be reduced by removing all burrs and sharp edges from the blank. Form blocks should be smooth; all sharp corners and projecting edges should be well rounded; high tooling pins should be eliminated; deep, narrow crevices or gaps between parts of form blocks should be eliminated; and holes in blocks should be plugged during forming.

**Procedure.** The sliding table containing the form blocks is loaded and slid into the press. Hydraulic fluid is pumped into the cell, expanding it and driving the rubber pad down against the workpiece and around the form blocks. The pressure is released, and the table of formed pieces is slid out, unloaded, and reloaded for another cycle.

Repositioning the form blocks after a few cycles will distribute the wear on the rubber pad and lengthen its life. The use of a hard-rubber (or

Fig. 11 Principal components of the Verson-Wheelon process

occasionally leather) pad slightly larger than the blank assists in the uniform forming of flanges and prevents wrinkles.

The cycle time for the Verson-Wheelon process is longer than that of conventional presses, such as those used with the Guerin process. To reduce cell filling and draining time, it is good practice to load the table to capacity or to have dummy blocks on the sliding table when only one part is being formed.

In the following example, the time to form a part in a Verson-Wheelon press was less than when the part was made by the Guerin process. The higher forming pressure completely formed the part in one operation (whereas, the Guerin process had required two operations) and reduced hand work after machine forming.

### Example 4: Verson-Wheelon versus Guerin Process for the Forming of a Complex Part.

The complex part shown in Fig. 12 was originally formed by the Guerin process in a 40 MN (4500 tonf) hydraulic press from 1.0 mm (0.040 in.) thick alclad aluminum alloy 7075-W. The improved method used a Verson-Wheelon press that could exert a pressure of 69 MPa (10 ksi) and had a capacity of 360 MN (41,000 tonf). A pressure of 48 MPa (7 ksi) was needed to form the part. The same tool was used for both processes.

In the Guerin process, forming was done in two operations. Joggles and stringer tabs were set by hand after forming. In the first press operation, the outer flange was formed, and the inner and return flanges were partly formed. In the second press operation, the forming was completed with rubber strips confined by the dams.

In the Verson-Wheelon process, the outer, inner, and return flanges and the joggles were formed in one operation. This translated into a 30% labor-cost advantage for the Verson-Wheelon process over the Guerin process for this workpiece.

The heat treated aluminum alloy 6061 form block was mounted to a baseplate, with the inner and outer rims acting as dams. Because of the return flange on the inside radius of the part, the aluminum alloy form block was split longitudinally, and the outer half was fastened to the

Fig. 12 Complex part that was formed in a Verson-Wheelon press. Dimensions given in inches

baseplate (see tooling setup in Fig. 12). The inner half, bushed and located on pins projecting from the baseplate, was removed from the base with the finished part. Locating holes in the blank and the outer form block matched locating pins in the cover plate.

The 127 by 2240 mm (5 by 88 in.) blank was routed, and lightening holes were individually pierced and flanged, in a punch press in both processes before rubber-pad forming. After forming, the part was aged to the T6 temper. The production lot was 20 pieces. Several thousand pieces were produced on the form blocks.

**Secondary Operations.** Even though higher forming pressures are used, many pieces made by the Verson-Wheelon process (as well as by the Guerin process) need hand work to remove wrinkles and to add definition to details. A further refinement in the use of throw pads is a shaped rubber pad. Pad laminations are built up around a cavity that approximates the shape of the part, so that flow of the rubber is less severe and forming pressure is more evenly distributed than with the conventional flat rubber pad. The shape of the cavity is only approximate and can be used for similar parts.

### Demarest Process

Cylindrical and conical parts can also be formed by a modified rubber bulging punch. The punch, equipped with a hydraulic cell, is placed inside the workpiece, which is in turn placed inside the die. Hydraulic pressure expands the punch. Forming with an expanding punch using the Demarest process is described in the following example.

**Example 5: Use of Expanding Punches to Form Aircraft Fuel-Tank Sections.** Aluminum alloy workpieces, rolled and welded into cones (Fig. 13a), were formed into aircraft fuel-tank sections with expanding rubber punches

**Fig. 13** Forming of a fuel-tank section from a blank using the Demarest process

(Fig. 13b). The cones were lowered into cast iron dies, which weighed 1600 kg (3500 lb) each and were designed to withstand 10 MPa (1.5 ksi) of forming pressure.

The rubber punch was lowered into the workpiece, and a steel cover was clamped over the whole assembly (Fig. 13c). The punch was expanded under 2800 kPa (400 psi) of hydraulic pressure, which formed the work metal into the curved shape of the die (Fig. 13d).

The time taken for the entire process, including dismantling of the die and unloading of the workpiece, was 3 min. In contrast, spinning requires 15 to 20 min.

### ASEA Quintus Fluid-Cell Process

The ASEA Quintus fluid-cell process is a further development of the Guerin process, allowing deeper and more complex parts to be formed. It uses a flexible rubber diaphragm backed up by oil as either the male or female tool half. The pressurized diaphragm forces the blanks to assume the shape of the solid-tool halves. The high uniform hydrostatic pressure permits the forming of shallow- to medium-depth parts with complex shapes to final shape, practically eliminating the subsequent hand forming usually required to apply the Guerin process.

**Presses.** The ASEA Quintus fluid-cell press (Fig. 14) consists of a horizontally placed cylindrical press frame, two rectangular, independently operated press tables on each side of the press, and all electric and hydraulic equipment necessary to operate the press placed on top of and alongside the press. The press frame is a forged steel cylinder that has been wound under prestress with high-strength steel wire, so that only compressional stresses can occur in the steel forgings, even at maximum pressure. Therefore,

the fatigue properties of the Quintus wire-wound frame are excellent and the risk of fracture virtually eliminated.

A diaphragm (bladder) of natural rubber is located inside the press and covers the entire surface of the press table. Hydraulic fluid is pumped into the cell created by the frame and the diaphragm, and the diaphragm is forced by the increased pressure to expand into the table, which forces the blank to assume the shape of the form block, thus forming the part. Once forming is done, the table is shuttled out to one side of the cylindrical press frame, and the table on the other side can be shuttled inside the press to allow forming of parts placed on that table.

ASEA Quintus fluid-cell presses are available with maximum forming pressures ranging from 100 to 200 MPa (14 to 29 ksi) and force capacities up to 1400 MN (157,000 tonf). The forming tables range in size from 700 by 2000 mm (27.5 by 78.7 in.) to 2000 by 5000 mm (78.7 by 196.8 in.). The large presses can accommodate tools as high as 425 mm (16.7 in.) and consequently form parts as deep or flanges as wide as 425 mm (16.7 in.).

**Personal Presses.** A new generation of Guerin-type press has been developed, called the personal hydropress. They are small presses and are well suited for small cells using lean-manufacturing principles. They generate pressures in the range of 14 to 21 MPa (2 to 3 ksi) and work well on less-complex parts. As the gage increases, the definition of the formed part is reduced. Aluminum parts with thicknesses up to 1.6 mm (0.063 in.) can be run on this new generation of press. The definition on joggles begins to deteriorate with thicknesses of approximately 1.27 mm (0.050 in.).

**Tools.** Because of the uniform hydrostatic pressure exerted by the press on the tools, they can be made of low-strength and low-cost tool materials such as hardwood, bakelite, epoxy,

**Fig. 14** Illustration of the principal components of a new-generation ASEA Quintus fluid-cell press. (a) Tray containing blanks inserted into press prior to pressurizing. (b) Pressurized fluid-cell diaphragm forming a blank

zinc alloy, and so on, as well as of stronger materials such as aluminum, cast iron, and steel. Depending on the shape of the part, and tolerance and surface finish requirements, parts can be formed over a male die (form block), in a female die, or in an expansion die. The side of a part requiring a high surface finish should face the diaphragm, while the side of a part requiring close tolerances should face the tool. Parts with complex shapes, tight radii or return flanges or made of high-strength materials, demanding high pressures, and parts required in large quantities may require tools of zinc or aluminum alloys.

**Procedure.** The ASEA Quintus fluid-cell press has two independently operated press tables. This allows parts to be unloaded and new blanks loaded on tools on one press table while parts are being formed on the other table inside the press. A press table can be loaded with one large single tool half occupying the full size of the table or several smaller tool halves; the number is restricted only by the size of the table.

Once blanks are loaded on the tools, the table is shuttled into the cylindrical press frame to a position where the flexible diaphragm, located in the upper half of the press, covers the entire table area. Oil is then pumped into the cell, causing the diaphragm to expand, which forces the blanks to assume the shapes of the tools. When the parts are formed, the pressure is relieved and the oil is evacuated from the cell, allowing the table to be shuttled out from the press so that parts can be unloaded from the tools. The cycle time for a Quintus fluid cell is usually 1 to 3 min, depending on the press size and forming pressure selected.

## Fluid Forming

In contrast to conventional two-die forming, which produces local stress concentrations in a workpiece, fluid forming (previously classified as rubber-diaphragm forming) employs a flexible-die technique that inhibits thinning and crack initiation due to the uniformly distributed pressure. In the fluid forming process, a rubber diaphragm serves as both the blankholder and a flexible-die member. Fluid forming differs from the rubber-pad and fluid-cell processes in that the

forming pressure can be controlled as a function of the draw depth of the part.

Fluid forming was initially known as the Hydroform process. The process, as originally conceived, is incorporated into the Verson Hydroform press. After a hydraulic pump delivers fluid under pressure into the pressure-dome cavity, the punch containing the die is driven upward into the cavity against the resistance provided by the fluid, and the workpiece is formed.

In the SAAB rubber-diaphragm method, hydraulic fluid being compressed by the press piston alone (no moving die is involved) forces the workpiece to assume the contour of the die. Air vents incorporated into the die facilitate the removal of trapped air and eliminate blisters on the surface of the workpiece. The ASEA Quintus fluid forming press was developed through slight modification of the SAAB process and optimization of press specifications with easily changeable pressure domes.

Another adaption of the fluid forming method is the ASEA Quintus technique used in the ASEA Quintus deep-drawing fluid forming press. Dome pressure and punch draw are both controlled from below the blank by two concentric rams, each of which governs one of these two variables. The units have interchangeable pressure domes.

Fluid forming is intended for punch, cavity, hydroblock, or expansion forming of deep-recessed parts (Fig. 15). Cycle time is 15 to 20 s for most parts.

## Verson Hydroform Process with Rubber Diaphragm

This process differs from those previously described in that the die cavity is not completely filled with rubber but with hydraulic fluid retained by a 65 mm (2½ in.) thick cup-shaped rubber diaphragm. This cavity is termed the pressure dome (Fig. 16). A replaceable wear sheet is cemented to the lower surface of the diaphragm, as shown in Fig. 16. More severe draws can be made by this method than in conventional draw dies because the oil pressure against the diaphragm causes the metal to be held tightly against the sides as well as against the top of the punch.

**Fig. 15** Four forming techniques that can be used in a fluid forming press. (a) Punch draw. (b) Cavity draw. (c) Hydroblock draw (male-die forming). (d) Expansion draw

Reductions in blank diameter of 60 to 70% are common for a first draw. When redrawing is necessary, reductions can reach 40%. Low-carbon steel, stainless steel, and aluminum in thicknesses from 0.25 to 1.65 mm (0.010 to 0.065 in.) are commonly formed. Parts made of heat-resistant alloys and copper alloys are also formed by this process.

**Presses.** A special press, called a Hydroform press, is used for this process. A lower hydraulic ram drives the punch upward; the upper ram is basically a positioning device. A hydraulic pump delivers fluid under pressure to the pressure dome. The blankholder is supported by a solid bolster and does not move during the operation.

Dome pressures range from 40 to 100 MPa (6 to 15 ksi), and punch force capacities vary from 3 to 19 MN (370 to 2090 tonf). Special guide pins and a platen adaptor convert a standard Hydroform press into a single-action conventional hydraulic press with a force capacity of 6 to 40 MN (700 to 4470 tonf). This variation of the process has the punch stationary and the blankholder actuated by the die cushion of a single-action hydraulic press, as shown in Fig. 20.

Maximum blank diameters are 300 to 1020 mm (12 to 40 in.), maximum punch diameters are 255 to 865 mm (10 to 34 in.), and maximum draw depths are 180 to 300 mm (7 to 12 in.). The maximum rating is 1500 cycles per hour. The practical production rate in cycles per hour is usually approximately two-thirds the machine rating. However, the operation often takes the place of two or three conventional press operations.

**Tools.** Punches can be made of tool steel, cold rolled steel, cast iron, zinc alloy, plastic, brass, aluminum, or hardwood. Choice of material depends largely on the work metal to be formed, number of parts to be made, shape of the part, and severity of the draw.

Blankholders are usually made of cast iron or steel and are hardened if necessary. Clearance between punch and blankholder is not critical; it may be 50% or more of the thickness of the metal being drawn.

For short runs, an auxiliary blankholding plate can be placed on a blankholder that is already in place. The auxiliary blankholder plate should not overhang in the punch clearance more than its thickness, and it should not be larger than the blankholder.

**Fig. 16** Fluid-cell forming in a Hydroform press with rubber diaphragm

Rubber strips are placed on the blank to break the vacuum caused by dome action during drawing. Blankholders can be contoured to match the shape of a preformed blank or to preform the blank as an aid in forming.

**Procedure.** The blank to be formed is placed on the blankholder. The pressure dome, filled with the hydraulic fluid and covered by the rubber diaphragm, is lowered over the blank, and preliminary pressure is applied through a pump in the hydraulic supply line. The preliminary pressure can range from 14 to 70 MPa (2 to 10 ksi), depending on the part to be formed.

The punch is raised and pushed into the blank from underneath. As the form in the blank rises into the hydraulic chamber, the pressure in the chamber increases sharply, reaching as high as 100 MPa (15 ksi). A pressure control valve keeps the pressure within programmed limits. When parts are formed of thin metal, a vacuum release valve can be built into the punch to aid stripping after forming.

Three cams are programmed to control the operation of the machine. The first controls the height of rise of the punch, the second controls edging or sharpening of the corner radii, and the third returns the punch at the end of the stroke while the blankholder strips the finished part from the punch. The forming of a complex part by the rubber-diaphragm process is described in the following example.

**Example 6: Rubber-Diaphragm Forming of a Complex Jet-Engine Part.** Fuel-nozzle swirl cups for high-performance turbojet engines were originally produced by welding six press-formed sections of type 310 stainless steel, AMS 5521 (Fig. 17a). Forming the six sections was difficult, and the finished parts were expensive. The rejection rate was also high.

**Fig. 17** Original and improved methods of forming a fuel-nozzle swirl cup for a turbojet engine. (a) Part formed by original method; six press-formed sections welded together. (b) Partly drawn blank ready for rubber-diaphragm forming. (c) Punch of six similar wedge-shaped segments doweled into bottom plate, used for rubber-diaphragm forming. (d) Swirl cup as formed by the rubber-diaphragm method and subsequently pierced and trimmed. Dimensions given in inches

Rubber-diaphragm forming in a Hydroform press was tried. This press formed the part from one blank 1.1 mm (0.043 in.) thick by 325 mm (12 $\frac{3}{4}$  in.) in diameter. Less press force was used, and costs were reduced 50%.

Before forming, the blank was rough drawn (Fig. 17b) in a 1330 kN (150 tonf) hydraulic press to a depth of 35.6 mm (1.40 in.), and its thickness was reduced to 0.99 mm (0.039 in.). After degreasing and annealing, the partly formed blank was drawn in a 305 mm (12 in.) Hydroform press, using the punch shown in Fig. 17(c). The blank rested on a blankholder mounted on a subbolster. Diametral clearance between punch and blankholder was a minimum of 50% of the work metal thickness. The production rate was 30 pieces per hour.

After forming, six equally spaced 36.50 mm (1.437 in.) diameter holes and a 63.50 mm (2.500 in.) diameter center hole were pierced in a 490 kN (55 tonf) mechanical press. The outside diameter was trimmed in a lathe after the part had been pierced, annealed, and restruck. The completed workpiece is shown in Fig. 17(d).

**Lubricants.** The following example shows the importance of the lubricant and its application when the depth of draw is near the limit for the rubber-diaphragm process.

**Example 7: Use of Lubricant to Eliminate Tearing and Wrinkling in Severe Rubber-Diaphragm Drawing.** The stepped cover shown in Fig. 18 represented the limit of forming severity for the rubber-diaphragm equipment that was available. The material was 1.0 mm (0.040 in.) thick cold rolled drawing-quality 1008 steel. The shell was 102 mm (4 in.) deep and had a step in its outer contour. Attempts to draw the stepped shell in one operation in a Hydroform press were not successful. Subsequently, two Hydroforming operations were developed in which the larger width of the cover was drawn first, and then the narrower portion

**Fig. 18** Drawing of a stepped cover by the fluid-cell process. Dimensions given in inches

above the step was produced in a redrawing operation to complete the part.

In the first operation, the blankholding pressure had to be carefully adjusted. When the pressure was too low, the metal moved freely and wrinkles appeared at the corners. Too high a blankholding pressure caused tears along the narrow end. Tears and wrinkles damaged the wear sheet and, in extreme cases, the diaphragm itself.

A lubrication program was developed that prevented wrinkling or tearing. After the first draw, the workpiece was cleaned, annealed, and phosphate coated. The phosphate made it possible to use a lighter oil and to apply it more effectively, with heavy applications in some areas and little or none in others. With experience, the operators became expert at judging the location and thickness of the lubricant. Mechanical application of lubricant could not be made selective enough or controlled closely enough for consistent results.

Because the part was nearly impossible to produce by conventional deep-drawing techniques, rubber-diaphragm forming was used. The tools, consisting of two punches and a blankholder, cost considerably less than the several sets of draw dies that would otherwise have been needed, and with the lubricating technique that was developed, there was less danger of tearing or wrinkling than by other processes.

**Surface Finish.** A major reason for using any rubber-pad process is to preserve the surface finish of the work metal, which would be scuffed or marked by ordinary press-forming tools. In the following example, appearance was an important consideration. The part was to be plated with copper-nickel-chromium. Forming by the rubber-diaphragm method prevented marks that would have been difficult to buff out before plating.

**Example 8: Use of a Rubber-Diaphragm Process to Preserve Surface Finish on a Flatiron Shell.** Because a mechanical draw press caused an impact line on the workpiece that was difficult to remove by buffing, production of the flatiron shell shown in Fig. 19 was

**Fig. 19** Flatiron shell that was formed by the fluid-cell process in a Hydroform press to preserve the surface finish. When this shell was drawn in conventional dies, an impact line was caused below the radius that was difficult to remove by buffing. Dimensions given in inches

changed to a rubber-diaphragm process, using a 3.6 MN (400 tonf) Hydroform press. A rubber draw ring of Durometer A 92 hardness helped adjust holddown pressure so that wrinkles were avoided in the finished product. Two rubber pads were used on the rubber diaphragm. One covered the diaphragm as a reinforcement and protector; the other was a 9.5 mm ( $\frac{3}{8}$  in.) thick ring molded to the shell outline. The blank was located in a nest on the blankholder.

Previously, the part had been drawn on a single-action mechanical press of 890 kN (100 tonf) capacity. In this press, the tools had been made of D2 tool steel. The stock was treated with soap and wiped with hydraulic oil near the point of the shell to minimize tearing.

The Hydroform press cycled at 450 strokes per minute. The production-lot size was 50,000 pieces, and yearly production was 850,000 pieces. Life of the rubber pads was as high as 20,000 pieces, and the finish of the part was good enough for subsequent plating with a minimum of buffing.

The sequence of operations was as follows: cut off blank, draw in Hydroform press, trim, pierce, copper plate, buff, nickel-chromium plate. The stock was  $0.84 \pm 0.08$  mm ( $0.033 \pm 0.003$  in.) thick cold rolled low-carbon steel sheet slit to width. Two different qualities of steel were used:

- Aluminum-killed drawing-quality special-surface steel with a commercial finish, dry, maximum hardness HRB 60
- Cold rolled aluminum-killed steel strip with a No. 2 finish, dry, dead soft, maximum hardness HRB 55

The tolerance on important dimensions was  $\pm 0.08$  mm ( $\pm 0.003$  in.); on angles,  $\pm 1/2^\circ$ .

**Single-Draw Operation.** In the following example, a pressure dome was mounted on the ram of a single-action hydraulic press. The punch was fixed to a shoe mounted on the bolster plate. A die cushion provided the blankholding force. This setup functioned much like a conventional draw die except that the oil-filled pressure dome and rubber diaphragm replaced the draw ring and die cavity.

**Example 9: Forming of an Automotive Tail-Lamp Housing in One Drawing Operation in a Rubber-Diaphragm Press.** An automotive tail-lamp housing was drawn in one operation from an aluminum alloy 5457-O blank 1.2 mm (0.048 in.) thick and 311 mm (12 1/4 in.) in diameter, in a rubber-diaphragm press rated at 69 MPa (10 ksi), as shown in Fig. 20. A water-soluble low-foaming lubricant was used. The production rate was 425 to 450 pieces per hour.

To produce this part with conventional tooling, two drawing operations would have been needed to form the sharp radii at the top and bottom of the part. Tooling costs for the rubber-diaphragm press were less than one-third the cost for conventional press tooling.

The blanks were moved from a stack adjacent to the press to an automatic feeder by a pneu-

matic suction transfer device. A photoelectric cell prevented more than one blank being transferred. The blank passed between lubricating rollers before being fed automatically into the die. In subsequent operations, the housing was trimmed, flanged, and pierced in a mechanical press, using two conventional dies.

### SAAB Rubber-Diaphragm Method

For some applications, the male member of a die set is made of rubber, and the female member is made of a hard material. In the Guerin process, shallow draws are made by recessing the form block and using the rubber pad as a punch to form the part (see the section "Shallow Drawing" in this article). The advantage of this method is that the flange is clamped before drawing, thus preventing wrinkling.

In the SAAB rubber-diaphragm method, hydraulic fluid is used behind a comparatively thin rubber pad or diaphragm. A hydraulic piston compresses the fluid against the rubber and forces the blank into the die, as shown in Fig. 21.

In all rubber-punch forming processes, air vents are provided in the die to allow the air trapped between workpiece and die to escape (Fig. 21). Without air vents, the trapped air would prevent the workpiece from reaching the full contours of the die, and the workpiece would have to be removed after partial forming to release the compressed air and then replaced in the same die to complete the forming.

**Fig. 20** Forming of an automotive tail-lamp housing in one draw in a fluid forming press. Dimensions given in inches

### Bulging Punches

Rubber punches can be used to make tubular parts that must be expanded or beaded somewhere along their lengths. If such parts were made with solid punches, the punches would have to be collapsible so that they could be withdrawn.

Hollow shapes can be bulged into suitable mating dies by applying a vertical force to the punch. The dies must be segmented so that the resulting bulged product can be removed, as shown in the following example.

**Example 10: Forming of a Mushroom Shape in a Segmented Bulging Die.** Figure 22 shows the process used in forming a mushroom-shaped frying-pan cover. The workpiece was a rectangular drawn shell of stainless steel, which was placed over a rubber punch of the same shape.

The two dies, which contained between them a cavity of the shape required, were closed until the rubber punch bulged the workpiece. The amount of bulge was determined by the depth of stroke. When the dies were opened, the punch returned to its original shape and was easily extracted from the finished part.

**Fig. 21** Principal components of SAAB rubber-diaphragm (fluid forming) method. The air vents keep trapped air from causing blisters on the workpiece.

**Fig. 22** Bulging of a mushroom shape from a pre-formed shell in a two-piece die with a rubber punch

### ASEA Quintus Fluid Forming Press

The ASEA Quintus fluid forming press is a vertical press having a circular fluid form unit that contains the rubber diaphragm and pressure medium (Fig. 23). These modular fluid form units serve the same function as the units used in the ASEA Quintus deep-drawing fluid forming press (see the section "ASEA Quintus Deep-Drawing Technique" in this article). The rigid tool half may be a male block, a cavity die, or an expansion die that is situated in a movable tool holder. Blanks are loaded onto the tool holder prior to shutting the holder into the press for the 10 to 50 s forming cycle required to produce the part.

For a 56 MN (6300 tonf) fluid forming press, two fluid form units designed for maximum 315 mm (12.4 in.) draw depth can be used. One unit, with a 63 MPa (9100 psi) forming pressure, has a 1090 mm (43 in.) blank diameter capacity. The other unit, providing a 160 MPa (23.2 ksi) forming pressure, has a 690 mm (27 in.) blank diameter capacity.

### ASEA Quintus Deep-Drawing Technique

Fluid forming has been optimized using the ASEA Quintus deep-drawing fluid forming technique, a variation of the SAAB rubber-diaphragm method. The ASEA Quintus fluid forming method incorporates two telescopic

rams: an outer ram to control dome pressure, and an inner ram to regulate the length of the punch draw (Fig. 24). Interchangeable domes, which require 20 min to change, allow the user to select a dome of optimal size and to avoid uneconomical use of an oversized dome when manufacturing small parts. Maximum forging pressure can also be increased by installing a smaller dome.

Each dome is a completely self-contained unit, with rubber diaphragms sealing off the pressure medium. Fluid form units for various pressure levels between 50 and 200 MPa (7.3 and 29 ksi) are available for each press size. Two or three such units should enable the user to make the most cost-effective use of the deep-drawing press. As an example, a set of interchangeable fluid form units for a 27 MN (3000 tonf) press ranges from an 800 mm (31.5 in.) diameter unit with a maximum 60 MPa (8.7 ksi) forming pressure to a 450 mm (17.7 in.) diameter unit with a maximum 190 MPa (27 ksi) forming pressure. Cycle time ranges from 10 to 60 s, depending on draw depth, part configuration, installed power, and selected pressure.

Complex shapes require accurate press control. As a result of 96 photocells that monitor the continuously varying pressure in the dome, greater accuracy and reliability are attained using a computer program to regulate the position and velocity of the draw depth. A paper cam cut with scissors gives dome pressure versus draw depth. The network of photocells reads the cam and governs an electrohydraulic control valve that controls the oil pressure in the outer cylinder, which is proportional to the dome pressure but much lower. By controlling the low

counteracting pressure instead of the dome pressure, increased accuracy and reliability are achieved.

Diameters to 2000 mm (79 in.) can be formed from blanks ranging from 0.1 to 16 mm (0.004 to 0.63 in.) thick. Draw ratios to 3:1 can be produced, making it possible to form a complex part in one operation.

### Other Methods of Hydraulic Forming (Ref 1)

Other methods for hydraulic forming of thin metal parts have used special machines such as diaphragm-forming hydrobuckling machines, or traditional presses such as gasket-draw and pressure-controlled machines, or more simple machines that are without gasket or control. The principles of different processes are discussed in the following.

**Hydraulic Forming with Diaphragm.** During the 1950s, this process was proposed on the market of special machines where oil pressure is applied by a synthetic rubber diaphragm on the metal to be formed (Fig. 25). Contrary to rubber stamping, where the elastic bulk is crushed by greatly increased local pressures (to the detriment of the sunken areas of the part), the pressure here is uniformly distributed, and very compact, concave, rounded forms result.

**Hydrobuckling.** The hydrobuckling process, patented by P. Cuq, can be included here because it incorporates metal-deformation control when there is minimum friction and an absence of thickness reduction. The part is formed by two combined actions, from a blank obtained by traditional drawing (Fig. 26). Hydraulic pressure ( $P$ ), created by a pump inside the part, flattens the metal against an exterior die or mold from collapsible load action ( $F$ ).

The pressure,  $P$ , is adjusted in ratio to the upstroke of the piston to fit the form, so that the metal areas that flatten the sunken parts of the mold are not obstructed by friction and therefore undergo no expansion—no thickness reduction. The word *buckling* is not quite suitable, because it implies a brutal, more-or-less controlled deformation.

This technique has been used for several years in the production of pulleys for automobile trapezoidal belts. In relation to the traditional

Fig. 28 Principal types of failure in curved flanges made by rubber-die forming

process (roller), the support facings of the belts show not even the slightest bulge.

**Hydraulic Forming with Gasket and Pressure Control.** This technique requires, in principle, nothing but a traditional machine—a double-effect hydraulic press (Fig. 27). Impermeability is ensured by means of a gasket between the die plate and the blank (or the flange), against which the blank grip leans. Pressure starts up when the punch goes into action, and its value is controlled during the entire operation in the leakproof chamber of the die cavity.

This process is most useful in making conical or vertical-wall draws, if there is enough play between the punch and the die to allow sufficient pressure to form metal beads around the punch

at the start of the operation. This pressure should be high: 30 to 50 MPa (300 to 500 bars) for soft steel, and 40 to 80 MPa (400 to 800 bars) for stainless steel. Here, the path of deformation becomes most important. A sheet has important deformation possibilities if it has been previously subjected to a restraining effort, but these possibilities are reduced if it has been subjected to expansion. The formation of beads around the punch can be compared with a beginning of return, or, again, to a first-draw blow corresponding to a less-severe reduction ratio. The metal starts deforming in the direction of restraint. In practice, it has been found that it is not always easy to define pressure control or the height of the beads.

## Failures in Rubber-Die Flanging

The rubber-pad forming of flanges can be performed within certain limits. The flange must be wide enough to develop sufficient bending force (Table 2) but not so wide as to exceed the permissible depth of the part. Figure 28 shows some typical flanging failures.

# Three-Roll Forming

THREE-ROLL FORMING is a process for forming plate, sheet, bars, beams, angles, or pipe into various shapes by passing the work metal between three properly spaced rolls. This article discusses sheet and plate, the mill products most often formed by the three-roll process.

**Shapes Produced.** Figure 1 illustrates some of the shapes commonly produced from flat stock by three-roll forming.

The plain round cylinder shown in Fig. 1 is used for pressure tanks, boilers, and related containers, and it represents a large portion of the shapes produced. The corrugated cylinder is produced in quantity for culvert pipe and is formed from flat stock corrugated at the mill. To retain the corrugations in the workpiece, the forming rolls also must be corrugated.

The flattened cylinder (obround) is primarily used for oil-supply tanks for heating systems and transformer cases. The elliptical cylinder is used for tank trucks hauling liquid food products, petroleum products, and chemicals.

Symmetrical and asymmetrical cones are both used in a wide variety of hoppers, bins, vertical storage tanks, concrete mixers, and vessels for chemical and food processing, as well as in piping and ductwork. In addition to the shapes produced for commercial use, three-roll forming is also used to produce various regular and irregular shapes for structural sections of submarines, aircraft, and nuclear reactors.

**Metals Formed.** Any metal ductile enough to be cold formed by other processes can be formed in a three-roll machine. Steels with a maximum carbon content of 0.25% constitute a major portion of the total tonnage used in three-roll forming. Steel sheet or plate in the 1010 to 1020 category is sometimes used, but most of the steels formed by this process conform to one of the plate specifications: either plain carbon or low-alloy steels, such as ASTM A515 grade 60, A515 grade 70, A516 grade 70, A285, A441, A283, A306, and A36. For the most successful three-roll forming, steels with a minimum elongation of 18% are preferred. Stainless steels, heat-resistant alloys, and aluminum and copper alloys can also be successfully formed by the three-roll process.

**Metal thicknesses** commonly used range from 1.5 mm (0.06 in.) sheet (16 gage) to 255 mm (10 in.) plate. In a few applications,

300 mm (12 in.) plate has been successfully formed. The principal factors limiting maximum thickness are the size and power of the rolling machine. Minimum thickness is typically limited only by handling equipment. Any sheet that can be handled without damage can usually be rolled.

It is impractical to roll thicknesses ranging from 1.5 to 255 mm (0.06 to 10 in.) on the same machine, although any machine can handle a relatively wide range of work metal thicknesses. For example, a machine capable of rolling 9.5 mm ( $\frac{3}{8}$  in.) plate (maximum or near maximum) can generally roll sheet as thin as 1.5 mm (0.06 in.), while a machine with a maximum capability for rolling 150 mm (6 in.) plate can successfully roll plate as thin as 13 mm ( $\frac{1}{2}$  in.)—even less on some machines.

**Diameter and Width.** The minimum diameter of a workpiece that can be successfully formed in a given machine is governed by the diameter of the top roll on either of the two types of machines used in three-roll forming—pinch type or pyramid type. In general, the smallest cylinder that can be rolled under optimal conditions is 50 mm (2 in.) larger in diameter than the top roll of a pinch-type machine. On a pyramid-type machine, the minimum workpiece diameter is rarely less than 150 mm (6 in.) greater than the top roll. However, more power is required to form sheet or plate into cylinders of minimum diameter than to form cylinders substantially larger than the top roll.

The maximum workpiece diameter that can be rolled is primarily limited by the space available above the machine to accommodate extremely large circles. Thin-gage metal rolled to a large diameter on horizontal rolls becomes less self-supporting as the workpiece diameter increases, and out-of-round cylinders will result if supports are not used. However, by using supports, almost any diameter can be rolled from thin metal. In general, 1.5 mm (0.06 in.) thick low-carbon steel sheet can be formed into cylinders as large as 120 cm (47 in.) in diameter without support, while 6.4 mm ( $\frac{1}{4}$  in.) thick low-carbon steel can be formed into cylinders as large as 210 cm (83 in.) in diameter without support.

The width (dimension of the work metal parallel with the axes of the rolls, designated as length in the formed cylinder) of sheet or plate that can be rolled is limited by the size of the

equipment; machines with rolls as long as 12 m (40 ft) have been built. The width-to-diameter relationship for workpieces that are extremely large in both directions is limited by problems in handling.

## Machines

There are two basic types of three-roll forming machines: the pinch-roll type and the pyramid-roll type. The rolls on most three-roll machines are positioned horizontally; a few vertical machines are used, primarily in shipyards. Vertical machines have one advantage over horizontal machines in forming scaly plate: Loose scale is less likely to become embedded in the work metal. With vertical rolls, however, it is difficult to handle wide sections that require careful support to avoid skewness in rolling. Most vertical machines have short rolls for fast unloading and are used for bending narrow plate, bars, and structural sections.

**Conventional pinch-type machines** have the roll arrangement shown in Fig. 2. For rolling flat stock up to approximately 25 mm (1 in.) thick, each roll is of the same diameter.

**Fig. 1** Typical shapes produced from flat stock by three-roll forming

However, on larger machines, the top rolls are sometimes smaller in diameter to maintain approximately the same surface speed on both the inside and outside surfaces of the plate being formed. These heavier machines are also supplied with a slip-friction drive on the front roll to permit slip, because of the differential in surface speed of the rolls. Therefore, as work metal thickness increases, the diameter of the top roll is decreased in relation to the diameter of the lower rolls.

The position of the top roll is fixed, while the lower front roll is adjustable vertically to suit the thickness of the blank. Optimal adjustment of the lower roll is important for gripping the stock and for minimizing the length of the flat areas on the workpiece. The rear, or bending, roll is adjustable angularly (usually  $30^\circ$  off vertical), as shown in Fig. 2. Angular movement of this roll determines the diameter of the cylinder to be formed.

All of the rolls are powered in most pinch-type machines. On some machines, however, only the two front rolls are powered, and the bending roll is rotated by friction between the roll and the work metal (Fig. 2). This arrangement is usually satisfactory in forming medium-to-heavy stock to large diameters. However, when forming sheet or plate that is thin or soft (or both) or when the diameter is large, the amount of friction is sometimes insufficient to rotate the bending roll. This condition can result in a marred surface if the work metal is soft or has a bright mill finish (aluminum sheet, for example).

A pinch-type machine can produce a more nearly true cylindrical shape than a pyramid-type machine because the work metal is held more firmly. This results in smaller flat areas on the leading and trailing ends of the workpiece.

As shown in Fig. 2, the work metal is fed to the powered pinch rolls (front), which grip the plate and move it through the machine. Forming begins when the work metal contacts the bending roll (rear) and is forced upward. As the forward motion of the workpiece continues, a cylindrical shape is produced, except for the unformed flat area along the leading end and a small flat area at the trailing end of the workpiece (Fig. 2). The width of the flat area on the trailing end usually ranges from  $1/2t$  to  $2t$  ( $t$ , work metal thickness), depending on the design of the machine.

**Fig. 2** End view of a cylindrical workpiece being rolled in a conventional pinch-type machine. Note the large flat area on the leading end and the smaller flat area on the trailing end.

In most pinch-roll forming, one of two procedures is used to minimize flat areas. The most common method is to preform both ends of the work metal in the machine. This is done by reversing the rotation of the rolls and feeding a short section of the work metal from the rear, thus preforming one end. The work metal is then removed from the machine; the formed section can be fed into the machine from the front, or it can be turned to the opposite unformed end and fed through from the rear of the machine. This procedure eliminates most of the flat areas.

Another method is to preform the leading and trailing ends of the work metal in a press brake, hydraulic press, or joggling press. However, this technique is seldom used, because it is usually more convenient to preform in the pinch-roll machine.

On the other hand, preforming in a press brake or in hydraulic or joggling presses can sometimes save time in the rolling machine, thus increasing the productivity of the machine. Additional advantages of a pinch-roll machine, as compared to a pyramid-roll machine, are:

- When all rolls are power driven, thinner sheets can be rolled, and cylinders can be formed to within approximately 50 mm (2 in.) of the diameter of the top roll.
- A given size of a pinch-type machine can roll a greater range of metal thicknesses because of the method of feed.
- Greater dimensional accuracy can be obtained in one pass in a pinch-type machine than in a pyramid-type machine.

The principal disadvantage of a pinch-roll machine is its unsuitability for rolling workpieces from angles, channels, and other structural forms.

**Shoe-Type Pinch-Roll Machines.** One important modification of the conventional three-roll pinch-type machine is the shoe-type machine, which uses the pinch principle and incorporates a forming shoe, as shown in Fig. 3. Because of the relationship of the two front rolls and the forming shoe to the workpiece, the flat area becomes barely discernible compared with the length of flat area obtained when rolling in a conventional machine (without preforming).

The shoe-type machine is often used to manufacture transformer cases and small tanks, such

**Fig. 3** End view of a cylindrical workpiece being rolled in a shoe-type machine with two powered rolls

as jackets for hot-water tanks. This type of machine can be completely automated; therefore, the work metal can be positioned on the table and fed into the machine automatically. During the work cycle, the cylinder is formed and ejected by means of an ejector mechanism and an automatically controlled drop end. Thus, a shoe-type machine is primarily a production machine that is used where large quantities of identical workpieces are to be rolled. For this reason and because of the limitations listed subsequently, shoe-type machines seldom compete directly with conventional pinch-type machines:

- Thickness of the work metal is limited to 12 gage (2.657 mm, or 0.1046 in.).
- Width of the sheet is limited to 183 cm (72 in.).
- Shoe-type machines are best adapted to the rolling of round cylinders; the rolling of ovals or obrounds is impractical.
- Shoe-type machines are applicable only to cold forming.

Within their range of applicability, however, shoe-type machines can produce a rolled cylinder in approximately half the time required in a conventional machine, primarily because preforming is not required with a shoe-type machine.

**Pyramid-Type Machines.** Figure 4 illustrates the arrangement of the rolls in a pyramid-type machine. The bottom rolls are of equal diameter but are approximately 50% smaller in diameter than the top roll. The bottom rolls are gear-driven and are normally fixed; each roll is supported by two smaller rolls (Fig. 4). The top roll is adjustable vertically to control the diameter of the cylinder formed. The top roll, which rotates freely, depends on friction with the work metal for rotation. Backup rolls are not used on the top roll.

As shown in Fig. 4, the work metal is placed on the bottom rolls while the top roll is in a raised position. The top roll is then lowered to contact and bend the work metal a predetermined amount, depending on the diameter of the

**Fig. 4** Arrangement of rolls in a pyramid-type machine. (a) Entrance of flat workpiece and shape of a nearly finished workpiece, including the flat areas on the leading and trailing ends. (b) Similar, except that the workpiece was prebent to minimize the flat areas on the ends

workpiece to be formed. Machines are usually equipped with a device that indicates the amount of initial bend. Some machines use an ammeter, which shows the amount of current used in forcing the roll downward. However, this device measures force only; variables in the work metal can cause differences in the amount of bend for a given force.

As required bending force increases, machines are designed with rolls of larger diameter, and the distance between centers of the bottom rolls increases. Bending forces are applied midway between the bottom rolls; therefore, less force is needed for a given deflection, but less curvature is produced.

Because the top roll is adjustable, pyramid rolls can be used for forming irregular shapes by bolting dies to the top roll—a technique that is not adaptable to pinch-type machines. In addition, plate, beams, angles, and other structural forms can be straightened with greater ease because the bottom rolls are on the same elevation.

The top roll is an idler; therefore, there are definite limitations on the minimum thickness of work metal that can be rolled (especially when forming large diameters). Adequate stiffness in the work metal is essential to provide enough friction to rotate the top roll. The minimum thickness that can be rolled varies, depending on the specific machine and the work metal composition.

Another disadvantage of the pyramid machine is the large flat areas that remain on both the leading and trailing ends of the work metal. Because the workpiece must remain supported by the bottom rolls at all times, the ends of the work can never get closer to the top roll than the distance between the points of tangency of the workpiece and the rolls. Therefore, it is impossible to eliminate these flat areas by rolling (Fig. 4a).

To minimize flat areas when using pyramid machines, the usual procedure is to preform the ends to the desired radius in a press brake or to roll an oversize blank, then trim the flat ends after. The shell can sometimes be returned to the rolls for truing after the seam has been joined. Occasionally, a narrow shim is placed at the ends to increase the bend radius, but care must be taken to avoid machine overload. The techniques used in forming with pyramid rolls make it more difficult to achieve the accuracy that is obtainable with pinch-type rolls.

**Capacity.** Three-roll forming machines are rated by the manufacturer according to the maximum thickness and width of low-carbon steel plate the machine can form at room temperature. Values are usually given for single-pass rolling, and allowances are then made for multiple-pass rolling. For example, a machine rated at 19 by 3660 mm ( $\frac{3}{4}$  by 144 in.) (thickness and width of plate, respectively) for work metal with a maximum tensile strength of 414 MPa (60 ksi) and capable of rolling plate to a diameter of 244 cm (96 in.) in a single pass can roll to a final diameter of 58 cm (23 in.) in multiple passes if

the top roll is no larger than approximately 37 cm ( $14\frac{1}{2}$  in.) in diameter.

If plate thickness is increased to 25 mm (1 in.), the same diameter restrictions would apply, but the allowable plate width would be reduced from 366 to 142 cm (144 to 56 in.) because of the additional power required for the increased thickness of work metal. At this point, another limitation may be encountered because the load imposed on the shorter surface area can become excessive as the plate becomes narrower and thicker. On the other hand, assuming all other factors remain constant, if plate thickness is reduced to 16 mm ( $\frac{5}{8}$  in.), the allowable width would revert to full capacity of the machine (366 cm, or 144 in.), but the rolled diameter could be reduced to 42 cm ( $16\frac{1}{2}$  in.).

The maximum plate thickness that can be handled by this machine depends on the pinch opening and is rated by the manufacturer of the machine. For example, some machines rated as described previously can accommodate work 38 mm ( $1\frac{1}{2}$  in.) thick, but for forming this thickness in a machine having the indicated capacity, the allowable plate width would be reduced to 53 cm (21 in.) because of the aforementioned factors. All of the previously mentioned calculations also take into consideration the limiting factor of roll deflection.

With all other conditions constant, power requirements increase according to the square of metal thickness. Therefore, the power required for forming plate 50 mm (20 in.) thick is four times as great as that required for forming 25 mm (1 in.) thick plate of the same width.

## Selection of Machine

Selection between pinch-type and pyramid-type machines depends mainly on the shape of the starting form and of the finished workpiece, the number of formed parts to be produced, accuracy requirements, and the cost. The pinch-type machine produces more accurate workpieces, and it can be loaded and unloaded much faster than the pyramid-type machine. Although both machines can produce shapes other than plain cylinders, the pinch type is capable of rolling a wider range of thicknesses. However, the pyramid-type machine is often preferred for small quantities of varied work, as in a job shop. Because of the wide space that can be obtained between the upper roll and the two lower rolls in a pyramid machine, various types of dies and fixtures can be fastened to the upper roll, thus permitting channels, angles, and various other structural shapes to be rolled or bent, either hot or cold.

## Rolls

Rolls used in three-roll forming machines are machined from steel forgings having a carbon content of 0.40 to 0.50% and a hardness of 160

to 210 HB. Plain carbon steel such as 1045 has often been used; when greater strength is needed, rolls are forged from an alloy steel such as 4340. Because the modulus of elasticity is the same for all carbon and low-alloy steels of medium carbon content, roll deflection for a given force will be the same.

Although the hardness range of 160 to 210 HB can be obtained by annealing, rolls with a microstructure obtained by quenching and tempering or by normalizing and tempering are less subject to surface deterioration from spalling. Therefore, the forged rolls are heat treated before being machined.

**Roll diameter** varies with the length and thickness of plate to be rolled. A typical top roll in a pinch-type machine, rated for forming steel plate up to 65 mm ( $2\frac{1}{2}$  in.) thick and 366 cm (144 in.) wide, would have a minimum diameter of 76 cm (30 in.). Journals for rolls of this diameter are approximately 43 cm (17 in.) in diameter.

**Crowning** of rolls to compensate for deflection is common practice. The amount of crowning is not necessarily the same for all rolls in a given machine. For example, in some machines, the rolls are not all of the same diameter; under these conditions, a roll that is smaller in diameter requires more crowning than a larger roll because the stress on all rolls is the same. When a machine is used for both light and heavy work, it is usual to crown the rolls for average conditions and then to use strips either at the center of the rolls to compensate for extreme deflection or at the ends to compensate for a lack of deflection (see the section "Roll Deflection" in this article).

**Roll Maintenance.** The extreme pressures to which rolls are subjected cause them to work harden. Rolls used in continuous production under high pressure sometimes elongate and reduce slightly in diameter. The amount of elongation or reduction in diameter is seldom significant, although the ends of rolls may require trimming after long periods of use.

There is no standard practice for reconditioning rolls. In some plants, rolls that have been subjected to long periods of severe service are trued by removing some or all of the work-hardened layer by turning. When required, the diameter is built up by welding an overlay on the rolls and then finish turning them. On the other hand, some manufacturers recommend that roll surfaces should never be turned. If the surfaces are spalled or otherwise damaged, any protruding metal should be removed by grinding. Although indentations in the rolls are less likely to be harmful, they may mark polished or clad surfaces. When rolling scaly plate, blowing away loose scale with an air lance is helpful in preventing scale from indenting the rolls or the work metal.

**Bearings and Lubricants.** Bronze has been successfully used for main bearings and is sometimes specified by the user. However, tin-base Babbitt is superior to bronze for most applications and is used in most machines.

Tin-base bearings are more compatible with the relatively soft steel journals at the pressures and speeds involved, and their ability to absorb particles of scale minimizes the possibility of scoring journals or bearings.

Extreme-pressure lubricants are recommended for the main bearings on all rolls, and a grade containing molybdenum disulfide is especially desirable. Because environmental conditions are likely to vary considerably where three-roll forming is done, the lubricant should have good pumpability over a range of temperatures. Extreme-pressure lubricants are satisfactory for both cold and hot forming.

## Preparation of Blanks

Blanks are usually cut to the desired size before forming. The length of plate (dimension of the work metal perpendicular to the axes of the rolls) required to form a given shape is determined by measuring the mean circumference (or perimeter, if the shape is other than a cylinder), which is the circumference taken at one-half the distance between the inside diameter and the outside diameter of the shape to be formed. This method of calculation is the one most generally used in both the cold and hot forming of plate.

**Allowance for Shift in Neutral Axis.** When greater accuracy is required, the more exact location of the neutral axis is considered when computing the blank, particularly if heavy plate thicknesses are involved. The neutral axis is the boundary between metal in tension and in compression and is usually one-quarter to one-half the thickness of the metal being bent, as measured from the inside of the bend. The exact location of this axis varies to some extent with the bend radius and the mechanical properties of the metal.

During cold forming, the neutral axis shifts inward from the mean by approximately 26% of the plate thickness. Therefore, for a 46 cm (18 in.) inside diameter (ID) cylinder, rolled from 13 mm ( $\frac{1}{2}$  in.) thick plate, the mean circumference is approximately 147.6 cm (58.12 in.), and for a 26% shift, the circumference at the neutral axis becomes 145.5 cm (57.30 in.). For a 46 cm (18 in.) ID cylinder of 6.4 mm ( $\frac{1}{4}$  in.) thick plate, the mean circumference is 145.6 cm (57.33 in.), and with a 26% shift, it changes to 144.6 cm (56.93 in.); the amount of shift is approximately one-half that for the 13 mm ( $\frac{1}{2}$  in.) thick plate. Therefore, the shift of neutral axis is usually disregarded for plate thicknesses less than 13 mm ( $\frac{1}{2}$  in.) except where greater accuracy is required.

In cold forming, the length of the blank is calculated by using a radius that is determined by subtracting 26% of the plate thickness from the mean radius or by adding 24% to the inside radius. When dimensional requirements are stringent, similar allowances are made for shift of the neutral axis and for thermal expansion in the hot forming of thick

plates (75 to 150 mm, or 3 to 6 in.) at 870 °C (1600 °F).

**Cutting of blanks** can be done by shearing, if shearing equipment is available for the width and thickness of the work metal. Gas cutting is commonly used for preparing blanks that are too thick for shearing. Additional information is available in the article "Shearing of Sheet, Strip, and Plate" in this Volume.

**Edge Preparation.** The cut edges of any plate (high-strength steel, in particular) can be a serious problem because of cracking during cold forming, which is cause for rejection of the workpiece. When plate is sheared, the edges are rough and often have surface cracks. Gas cutting usually produces smoother edges, but the edges of gas-cut steel plate will frequently be hardened in cooling from the cutting temperature. Therefore, nucleation sites for cracks are likely to be present from either method of cutting.

The danger from cracking caused by rough edges increases as plate thickness increases and the finished diameter of the cylinder decreases. Because the plate surface that forms the outside diameter of the cylinder is in tension during forming, cracks propagate from edges, which are in tension.

On plate 25 mm (1 in.) or more in thickness, the edges indicated in Fig. 5 should be removed before cold forming. This is not required before hot forming. Usual practice is to employ a chipping hammer and then a portable grinder to smooth the edges. The amount of metal removed is usually negligible, and a slight bevel on the critical edges is sufficient. If a substantial amount of metal is to be removed, allowance must be made for it when calculating the dimensions of the blank.

## Cold versus Hot Forming

Because cold forming involves fewer problems and is less costly than hot forming, it is preferred practice to form workpieces at room temperature. In hot forming, dimensional accuracy is more difficult to control, and cost is significantly increased by:

- Heating the blank
- Handling both the blank and the workpiece while the metal is hot

**Fig. 5** Sheared or gas-cut blank, showing where metal should be removed from edges before cold forming, to reduce susceptibility to cracking

- The necessity for restoring acceptable surfaces by pickling, blast cleaning, or other surface treatment
- The accelerated rate of deterioration of rolls and other equipment because of contact with hot metal

**Forming Capacity.** When carbon or low-alloy steel is heated, tensile strength decreases and formability increases. Heating the work metal therefore extends the usefulness of a roll-forming machine. For example, a 3 m (10 ft) long pinch-type machine with 495 mm (19½ in.) diameter rolls can form a 366 cm (144 in.) diameter cylinder from 64 mm (2½ in.) thick by 62 cm (24½ in.) wide plate at room temperature in one pass (assuming the work metal has a tensile strength of 410 MPa, or 60 ksi, at room temperature). With all other conditions remaining constant, by heating the work metal to a temperature high enough to reduce the tensile strength to 70 MPa (10 ksi) or lower, the width of the plate (measured parallel to the roll axes) can be increased to 210 cm (82 in.) and rolled in one pass, using the same amount of power needed for rolling plate 62 cm (24½ in.) wide at room temperature. To reduce the tensile strength of low-carbon steel and to obtain optimal formability, the usual practice is to heat the steel to 870 °C (1600 °F).

Similarly, the size of the machine described previously is capable of cold forming a 366 cm (144 in.) diameter cylinder from 44 mm (1¾ in.) thick by 150 cm (60 in.) wide low-carbon steel plate in one pass. Under the same conditions, except for heating to 870 °C (1600 °F), the thickness of the plate can be increased to 70 mm (2¾ in.).

One method of evaluating the difference in formability between cold and hot rolling is to measure the force required to form a given plate. This is done on pyramid-type rolls by measuring, in terms of amperage, the downward force on the upper roll and the force required to rotate the powered rolls (Fig. 6). The following example

**Fig. 6** Comparison of current flow (proportional to force) measured on screw and rolls during cold rolling and during the rolling of 44 mm (1¾ in.) thick plate preheated to 870 °C (1600 °F). Dimensions given in inches

demonstrates the difference in current flow, number of passes, and time needed for the cold and hot forming of similar cylinders.

**Example 1: Cold versus Hot Forming of 44 mm (3/4 in.) Thick Steel Plate.** A pyramid-type machine was used to produce 64 cm (25 1/4 in.) ID by 110 cm (43 3/8 in.) long cylinders from 1020 steel blanks 44 mm (1 3/4 in.) thick by 110 cm (43 3/8 in.) wide by 215 cm (84 1/2 in.) long. When forming was done at room temperature, 25 passes were required with current flow on the upper roll (screw) and power rolls as shown in Fig. 6. Rolling time was 40 min per cylinder. When blanks were heated to 870 °C (1600 °F) and finished at 565 °C (1050 °F), the number of passes was reduced to 12 and rolling time to 11 min per cylinder. Current flow was also reduced, as shown in Fig. 6.

**Hot Forming Formability Problems.** The technique described in the preceding example for increasing the effective capacity of equipment by hot forming does not apply to all metals, and the amount of decrease in tensile strength varies considerably among carbon and low-alloy steels. For example, heat-resistant alloys, by definition, resist the softening effect of heat, and many of these alloys precipitation harden in the temperature range that would be used for the hot forming of carbon steel (see the article "Forming of Nickel and Cobalt Sheet Alloys" in this Volume). Magnesium and titanium alloys are usually formed at the same elevated temperature used to form the same alloy by other methods (see the articles "Forming of Magnesium Alloys" and "Forming of Titanium and Titanium Alloys" in this Volume). Copper and aluminum alloys are usually formed at room temperature. However, alloys 7075 and 7079, as well as some other precipitation-hardening alloys, must be formed within 24 h after solution treatment. If forming cannot be done within this length of time, the work metal must be stored at -12 °C (-10 °F) to prevent precipitation hardening (see the articles "Forming of Aluminum Alloys" and "Forming of Copper and Copper Alloys" in this Volume).

**Maximum Elongation.** In many applications with steel, hot forming is mandatory regardless of the capacity of available forming equipment. Common practice is to compute a maximum elongation in the outer surface for cold forming, as determined by:

$$E = \left( \frac{t}{d+t} \right) 100 \quad (\text{Eq 1})$$

where  $E$  is the percentage of elongation in the outer surface of the cylinder,  $d$  is the inside diameter of the cylinder (in inches), and  $t$  is the plate thickness (in inches). For example, for a cylinder having an inside diameter of 145 cm (57 in.) to be formed from 75 mm (3 in.) thick steel plate:

$$E = \left( \frac{3}{57+3} \right) 100 = 5\% \quad (\text{Eq 2})$$

Elongation of more than 5% (determined by Eq 2) is seldom permitted for cold forming, and the maximum is often 3.5%. If the maximum permissible elongation was 3.5% in the aforementioned example, either the minimum cylinder diameter would be near 210 cm (83 in.) or the plate thickness would have to be reduced before cold forming would be permitted. Maximum elongation is established by the user of the formed product, and hot forming is used when specifications cannot be met by cold forming.

**Combination Hot and Cold Forming.** A combination of hot and cold forming is sometimes advantageous and permits elongation requirements to be met. For example, in forming the 145 cm (57 in.) diameter cylinder described previously, one procedure is first to hot form the 75 mm (3 in.) thick plate to a circular segment of approximately 230 cm (90 in.), allow the workpiece to cool to room temperature, and then clean and finish form at room temperature. This procedure makes it possible to meet more severe elongation requirements and to retain some of the advantages of cold forming, such as greater accuracy.

## Hot Forming Temperatures for Steel

Carbon or low-alloy steel plate is commonly heated to 870 °C (1600 °F) for hot forming after normalizing at the mill. However, plate in the as-rolled condition is less costly. The as-rolled steel is normalized while it is being heated for forming and cooled during forming. In such an operation, the steel is heated to 900 to 925 °C (1650 to 1700 °F), instead of to 870 °C (1600 °F), before forming.

**Finishing temperature** is critical for some steels, especially the plain carbon grades, because of the blue-brittle temperature range. It is generally recommended that the finish-rolling temperature should be 565 °C (1050 °F) or higher. If the workpiece cannot be completely formed before it cools to 565 °C (1050 °F), it should be removed from the machine and reheated.

**Warm forming** is often used when forming requirements are too severe for room temperature and when heating to the conventional hot forming temperature cannot be permitted because the mechanical properties of the steel would be impaired. A notable example is the forming of quenched-and-tempered grades of high-strength low-alloy steel. Common practice is to heat these steels no higher than the temperatures at which they were tempered and then form at once.

## Power Requirements

The power required to form a given cylinder on three-roll equipment depends on the strength of the work metal, plate thickness, plate width, finished diameter of the cylinder, number of

passes used, and temperature (hot or cold forming).

**Strength** of the work metal, plate thickness, and plate width (measured parallel to the roll axes) determine the diameter of a cylinder that can be formed in a given machine. The curves in Fig. 7, for a 3 m (10 ft) long pinch-type roll machine with 483 mm (19 1/2 in.) diameter rolls, represent combinations of maximum plate thickness and width that can be rolled at room temperature into cylinders of 365 cm (144 in.) in diameter or larger in a single pass. The significant influence of the strength of the steel is evident from Fig. 7. For example, 38 mm (1.5 in.) thick low-carbon steel plate of 410 MPa (60 ksi) tensile strength can be rolled into 365 cm (144 in.) diameter cylinders in one pass in widths up to 305 cm (120 in.) in this machine. Under similar conditions, the width of 38 mm (1.5 in.) thick high-strength low-alloy steel that can be formed to the same cylinder diameter is restricted to approximately 56 cm (22 in.) (Fig. 7). The machine used was rated at 65 mm (2.5 in.) by 300 cm (120 in.).

**Work Hardening.** Most metals are susceptible to strengthening by cold work (work hardening), although the extent to which metals are affected varies widely among the various compositions. Of the steels commonly processed by three-roll forming, those of low carbon content, such as 1010, are least susceptible to work hardening and seldom present any serious problems. As carbon or alloy content increases, the rate of work hardening increases.

For metals that work harden rapidly, power consumption increases as forming proceeds. Eventually, the machine is overloaded, or the work metal fractures.

**Intermediate annealing** must be used when work-hardenable metal is severely formed. For

**Fig. 7** Interrelationship of cylinder height ( $h$ ), thickness ( $t$ ), and work metal strength for forming in a single pass in a pinch-type roll machine at room temperature. TS, tensile strength; YS, yield strength

steel, full annealing is usually recommended. Process (subcritical) annealing is sometimes used. However, process annealing alternated with cold work is likely to result in excessive grain growth and subsequent poor formability, despite the hardness.

**Cylinder Diameter.** With other conditions constant, power requirements increase as cylinder diameter decreases when the cylinder is completely formed in one pass. However, the use of two or more passes (up to 12 is not uncommon) permits the rolling of smaller-diameter cylinders without increasing machine size. For example, Fig. 7 shows that 38 mm (1.5 in.) thick by 305 cm (120 in.) wide plate of low-carbon steel can be formed into a cylinder 366 cm (144 in.) in diameter in one pass on a given machine. By using 10 or 12 passes, cylinders as small as 65 cm (25½ in.) in diameter have been formed from the maximum thicknesses shown in Fig. 7. For plate thickness of 30 mm (1⅜ in.) or less, cylinders as small as 55 cm (21½ in.) in diameter can be formed in multiple passes.

Similarly, for carbon steel having a tensile strength to 590 MPa (85 ksi) and stainless steel to 830 MPa (120 ksi), any of the plate thicknesses shown in Fig. 7 can be rolled to cylinders as small as 70 cm (27½ in.) in diameter. For steels having a tensile strength of approximately 500 MPa (72 ksi), plate thicknesses of 28 mm (1⅜ in.) or less can be rolled to cylinders 56 cm (22 in.) in diameter, using the multiple-pass procedure. The plate thickness limitations for rolling 56 cm (22 in.) diameter cylinders then decrease to 26 mm (1⅜ in.) (maximum) for steel with a tensile strength of 590 MPa (85 ksi) and to 21 mm (1⅜ in.) for stainless steel with a tensile strength of approximately 830 MPa (120 ksi).

Power requirements for quenched-and-tempered high-strength low-alloy steel (970 MPa, or 140 ksi, in Fig. 7) are high, and there is an increased probability of cracking. Suggested limits for maximum plate thickness and minimum cylinder diameter for multiple-pass rolling, regardless of power, are:

Maximum plate thickness		Minimum cylinder diameter	
mm	in.	mm	in.
25	1	1170	46
19	¾	890	35
13	½	825	32½
9.5	⅜	775	30½
6.4	¼	710	28

**Temperature.** The limitations imposed by steel composition and other factors shown in Fig. 7 are markedly changed when the work metal is heated (see the section “Cold versus Hot Forming” and example 1 in this article). However, it is not always possible to use hot forming—for example, for quenched-and-tempered high-strength low-alloy steel (see the section “Warm Forming” in this article).

## Forming Small Cylinders

The cold forming of small cylinders by the three-roll process requires extra care, especially when the diameter of the cylinder to be formed is near that of the rolls. The rolling of cylinders having an inside diameter of less than 50 mm (2 in.) more than the outside diameter of the roll is not generally recommended. However, a skilled operator, using special care, can form cylinders within 38 mm (1½ in.) in diameter in a pinch-type machine.

## Forming Large Cylinders

Cylinders that are large in diameter or in length can be formed by the three-roll process. Some special procedures may be required, especially when the sheet is so thin that the cylinder cannot retain a round shape without support. Under these conditions, overhead cranes or temporary braces or both can be used for support.

When flat blanks of the required length are unavailable, two or more sections can be welded together to obtain the required length. The following example describes this practice in the forming of large cylinders.

**Example 2: Forming 472 cm (186 in.) Outside Diameter Cylinders in a Pinch-Type Machine.** Cylinders 472 cm (186 in.) in diameter and 284 cm (112 in.) long were formed from blanks prepared by welding together three sections of copper-clad low-carbon steel. The fabricated blanks were 1480 cm (582¾ in.) long by 284 cm (112 in.) wide by 14 mm (⅝ in.) thick. The cylinders were formed cold on a 19 mm (¾ in.) by 3.7 m (12 ft) pinch-type machine. The major problem in this operation was support because the work was not thick enough to provide natural support. Overhead cranes were used to hold the formed section of the plate during rolling. The ends of the cylinder were tack welded before the workpiece was removed from the machine. Temporary braces were then used to hold the cylinders in a near-round condition while the seam was welded. After welding, outside rounding rings made from 38 by 125 mm (1½ by 5 in.) rectangular steel bars were used to hold the cylinder shape for subsequent attachment to other cylinders. In use, the welded internal parts stiffened the assembly.

## Forming Truncated Cones

Pyramid-type machines are generally used in the forming of truncated cones. There are two basic limitations on the shape of conical configurations that can be formed by the three-roll process. First, the smaller diameter (A, Fig. 8) must be large enough to maintain the established workpiece-to-roll relationship on minimum obtainable diameter, and second, the plate must

be thick enough to be formed by the holdback method shown in Fig. 8 so that the pressure buildup on the holdback pin does not upset the plate edge or damage the holdback attachment or both.

The size of cone that can be formed depends largely on the pitch, the spacing and length of rolls, and the diameter of the upper roll. As the cone height increases, difficulties in getting the large diameter to follow the small diameter accurately also increase. If the lower roll spacing is too wide, the size of the smaller diameter will be severely limited, because as the work metal passes the holdback pin (Fig. 8), it will curve into the housing that supports the rolls and rolling will be impossible.

**Procedure.** There are several significant differences between forming conical shapes and forming cylinders by the pyramid-type three-roll process. In rolling cylinders, the blank is rectangular and is rolled in a direction perpendicular to the rolls. In contrast, curved blanks are used for conical shapes, and they are rolled on a curve. In addition, no pin is needed in rolling cylinders, and the top roll is pitched for forming cones but is straight and level when forming cylinders.

Before the developed blank is placed in the pyramid-type three-roll machine for forming a cone, the ends of the blank are preformed in a pinch-type roll from the rear or in a press brake. For forming the cone, the top roll is pitched as shown in Fig. 8. As the rolls drive the blank, its edge drags around the pin, and the various diameters of the cone are formed. The blank is then rolled in multiple passes, dragging around the pin until the ends of the blank are closed. If the pitch of the rolls matches the pitch of the entire length of the cone, a nearly true cone will result.

Truncated cones are sometimes produced by forming two semicircular half-cones and welding them together; the completed workpiece has two longitudinal seams instead of one. In another method, two or more circular tapered sections are formed and welded together. When produced by this method, the finished cone has

**Fig. 8** Rolling a truncated cone in a three-roll pyramid-type machine from a blank with preformed ends

one longitudinal seam and one or more circumferential seams.

## Forming Bars and Shapes

Pyramid rolls and machines with overhanging rolls are used to form bars, bar sections, and structural shapes into circles. Shapes that can be processed by this method include rounds, squares, flats (on the edge or on the flat), I-beams, L-shaped structurals, and channels. Hardened roll sections that are adjustable to the thickness or cross section of the shape are used (Fig. 9). Some bars or shapes can be formed with plain, flat rolls, but more often rolls conforming to the shape of the unformed workpiece are required.

The rolls are adjusted to produce the required workpiece diameter in the same manner as in rolling cylinders from sheet or plate. Prebending the ends and rolling the workpiece back and forth are also employed in the three-roll forming of bars and shapes. A significant difference in the rolling of bars and shapes is the frequent use of guide rollers or guide fingers or both, mounted so as to contact the sides of the workpiece and prevent it from twisting during forming.

One of the most difficult shapes to form by the three-roll process is an angle with one leg inside the circle (Fig. 9). When forming this shape, spiraling, twisting, buckling of the inside leg, and reduction of the angle between the two legs are likely to occur. These difficulties can be minimized by using a hardened upper roll having a removable end plate and a spacer that is not more than 0.81 mm ( $1/32$  in.) thicker than one leg of the angle (Fig. 9). The radius on the upper roll ( $R$ , Fig. 9) must conform to the fillet radius of the angle to be rolled. The other end of this roll ( $R_1$ , Fig. 9) can have the same radius or a radius conforming to another angle to be rolled. This end of the upper roll can be used by reversing the roll end for end. In production rolling of the same angle, common practice is to have the same values for  $R$  and  $R_1$  (Fig. 9), thus permitting double the roll life by reversing the roll. Guide rollers and fingers (not required for the section shown in Fig. 9) also help to produce accurate circles from bar sections.

## Out-of-Roundness

Out-of-roundness, or ovality, of cylinders produced by three-roll forming is caused by one or more of the following variables:

- Varying thickness of the flat blank
- Varying hardness within the blank
- Overforming or underforming of the ends in the preforming operation
- Springback of the work metal
- Temperature of the metal being formed
- Number of passes
- Condition of the equipment
- Operator skill

The most important of the aforementioned factors is operator skill; condition of the equipment is also a major factor.

Variations in the mill product (thickness and hardness within a single sheet or plate) are seldom great enough to warrant the extra cost that would be necessary for closer-than-normal control of the work metal. Out-of-roundness and other dimensional variations in the product increase as workpiece diameter increases. Plate thickness above or below the actual crown thickness of the rolls can also cause dimensional variations. For large or small workpieces, much out-of-roundness is caused by variations in preforming the ends, regardless of whether pinch rolls or press brakes are used in preforming.

Springback is overcome by forming to a circle smaller than that required for the finished cylinder. However, the overforming of high-springback material must be done with caution; as the elastic limit is exceeded, metals will take a permanent set, and too much overforming can result.

**Hot forming** may contribute to out-of-roundness because considerable plastic flow can take place when a steel workpiece is heated to 870 °C (1600 °F) or higher. The amount of plastic flow varies as the bending load is applied during forming, and variations are increased by uneven cooling of the work metal. Resulting variations in plate thickness and curvature contribute to out-of-roundness.

**Production Example.** Without the use of special techniques or secondary operations, there is likely to be considerable variation in out-of-roundness among workpieces that are intended to be identical and are produced under the same conditions. This is demonstrated in the following example.

**Example 3: Out-of-Roundness Variations in 44 Cylinders, 432 mm (17 in.) in Diameter.** Cylinders 432 mm (17 in.) in diameter were produced on a pinch-type machine in one

**Fig. 9** Roll setup for forming an angle section into a circle. Guide rolls and guide fingers are not required for this application.

pass. Leading edges of the blanks were prebent 15° for a distance of 50 mm (2 in.) with a 102 mm (4 in.) radius. After the cylinders were formed and tack welded, measurements were taken. Out-of-roundness variation in 44 cylinders is plotted in Fig. 10.

**The number of passes** used to form a given cylinder can have a significant effect on out-of-roundness. In most applications, two or more passes (sometimes as many as 12) will produce cylinders that are more nearly true round than those formed in a single pass.

**Methods of Correction.** The most effective method for correcting out-of-roundness is to reroll the cylinder carefully before welding. This operation causes a one-third greater load on the machine than the original rolling.

For cylinders having wall thickness no greater than approximately 9.5 mm ( $3/8$  in.), a draw-down type of expander applied after rolling and welding is an effective means of correcting out-of-roundness.

If design permits, beads or flanges can be rolled into the cylinder wall to reinforce it and to help maintain roundness. Oil drums are examples of the effective use of this technique. When dimensional requirements are plus or minus a few thousandths of an inch, stock must be allowed for machine boring the cylinder to the specified diameter.

## Forming Speed

The speed of forming is a critical factor in product quality. Low-carbon steel plate up to 8 mm ( $5/16$  in.) thick is sometimes rolled at speeds to 18 m/min (60 ft/min). For a speed this high, however, workpiece diameter is necessarily medium to large, because it is impractical to control the machine for rolling small diameters at high speed.

The most commonly used speeds for cold forming (particularly for thick plate) range from 3.6 to 6 m/min (12 to 20 ft/min). This range is usually maintained in both cold and hot forming; however, to complete hot forming with a minimum decrease in temperature of the work metal, it is sometimes necessary to increase the speed of the bending roll.

## Roll Deflection

Roll deflection can be calculated by standard formulas, considering the roll as a simple beam

**Fig. 10** Out-of-roundness variations in 44 cylinders of the same diameter produced in a pinch-type roll machine. Dimensions given in inches

supported at both ends. On pyramid rolls, deflection is often minimized by support rollers applied to the lower rolls. These rolls act as backup rolls.

In forming heavy plate, pressures are high and all three rolls are crowned (made larger at the centers than at the ends). Crowning is necessary because the rolls deflect under the bending load; if they were straight, all formed cylinders would bulge somewhat at the center. Because the amount of deflection depends on the bending load, usual practice is to crown the rolls enough to compensate for the average job in the plant. When forming plate thicker than the actual crown deflection, the rolls are shimmed by running strips of thin metal (16, 14, 12, or 10 gage) between the rolls and the inside diameter of the workpiece at the center of the rolls. This shimming compensates for excessive deflection.

When forming metal that is too thin to cause deflection of the rolls, crowning will cause the formed cylinder to be larger in diameter at the ends than in the center. Correction can be made by shimming the ends of the rolls in a manner similar to that described previously for shimming the centers.

## Alternative Processes

Three-roll forming is the most practical method of producing large cylinders and truncated cones from heavy plate.

**Deep drawing** is often the most economical method of producing small cylinders from sheet no thicker than 3.18 mm (0.125 in.). Seamless cylinders or cones can be produced by deep drawing, piercing, and trimming (see the article "Deep Drawing" in this Volume). However, as cylinder size or wall thickness increases, forming by deep drawing becomes impracticable. In some applications, three-roll forming and welding are preferred for producing a hollow shape from stock that is substantially thinner than 3.18 mm (0.125 in.).

**Contour Roll Forming.** Theoretically, the diameter and length of straight cylinders producible by contour roll forming are almost unlimited. In practice, however, diameter and wall thickness are limited by the size of available equipment. Contour roll forming is rarely used for rolling metal thicker than 6.35 mm (0.250 in.) and is most often used for thicknesses less than 3.18 mm (0.125 in.). Therefore, contour roll forming is impractical for producing large heavy-wall cylinders (see the article "Contour Roll Forming" in this Volume).

**Forming two halves** (semicircles) between dies in a press and then welding the two half-cylinders is sometimes practical. However, even when presses of sufficient size are available for forming large plate, die cost is likely to be prohibitive. For limited production, a press brake is often used to produce semicircles that can subsequently be joined by welding into cylinders.

## Safety

Forming rolls move relatively slowly but require protection for the operator. The most positive method of protection is to cover the nip point between the feed rolls. One effective guarding device is a solid metal plate covering the nip point between the feed table and the rolls for the full length of the rolls. This plate, with a stud welded to each end, is attached to slotted vertical brackets by nuts and washers so that it is adjustable vertically. The brackets are securely fastened to the feed table.

The height of the feed table can be made adjustable by welding a nut to the lower end of each tubular leg. A long bolt, with a large washer welded to the top of the head, is screwed into the nut to achieve the desired height. A locknut can be used to prevent the bolt from turning because of vibration.

Emergency tripping bars connected to electric cutoff switches or, preferably, to reverse electric switches can be used to stop the rolls. The bars may be at knee level in front of the operator, or directly in front of the bottom feed roll and far enough below the feed point to avoid accidental tripping.

Feeding guides for narrow workpieces can be made of bar stock or angles that are bolted to the feed table. The guides should be slotted for ease of adjustment to various widths of workpieces.

# Contour Roll Forming

CONTOUR ROLL FORMING (also known as roll forming or cold roll forming) is a continuous process for forming metal from sheet, strip, or coiled stock into desired shapes of uniform cross section by feeding the stock through a series of roll stations equipped with contoured rolls (sometimes called roller dies). There are two or more rolls per station. Most contour roll forming is done by working the stock progressively in two or more stations until the finished shape is produced.

Only bending takes place in contour roll forming; the stock thickness is unchanged except for a slight thinning at bend radii. The process is particularly suited to the production of large quantities and long lengths to close tolerances and involves a minimum of handling. Auxiliary operations, such as notching, slotting, punching, embossing, curving, and coiling, can easily be combined with contour roll forming.

Contour roll forming is used in many diverse industries to produce a variety of shapes and products. The process is also used for parts that were previously manufactured by extrusion processes. This use is limited, however, to parts that can be redesigned to have a constant wall thickness. Industries that use roll-formed products include the automotive; building; office furniture; home appliance and home product; medical; railcar; aircraft; and heating, ventilation, and air conditioning industries.

Contour roll forming can be divided into two broad categories: a process using precut lengths of work metal (precut or cut-to-length method) and a process that uses coil stock that is trimmed to size after forming (postcut method).

In precut operations, the work metal is cut to length before entering the forming machine. The precut process usually employs a stacking and feeding system to move blanks into the machine, a contour roll-forming machine operating at a fixed speed of about 15 to 75 m/min (50 to 250 ft/min), an exit conveyor, and a stacking system. The precut method is primarily used for low-volume operations and when notching cannot be easily accomplished in a postcut line. Often, the material is run from a coil to a shear or blanking press and then fed mechanically to the contour roll former.

Tooling for the precut method is relatively inexpensive because cutting requires only a flat shear die or an end notch die. End flare is more pronounced than it is with the postcut method, however, and side roll tooling is required to obtain a good finished shape.

The most efficient, productive, and consistent contour roll forming process is the postcut method. This method requires an uncoiler, a roll-forming machine, a cutoff machine, and a runout table (Fig. 1). Postcut contour roll forming can be augmented by various auxiliary operations,

such as prenotching, punching, embossing, marking, trimming, welding, curving, coiling, and die forming. These auxiliary operations can be used to eliminate the need for subsequent operations, resulting in production of a finished product.

Tooling cost and tooling changeover time are greater for the postcut method than is the case with precut operations, but the increased efficiency of the postcut process balances this limitation.

## Materials

Any material that can withstand bending to the desired radius can be contour roll formed. Thicknesses of 0.13 to 19 mm (0.005 to  $\frac{3}{4}$  in.) and material widths of 3.2 to 1830 mm ( $\frac{1}{8}$  to 72 in.) can be used. Length of the formed part is limited only by the length that can be conveniently handled after forming.

In some cases, multiple sections can be formed from a single strip; in other cases, several strips can be fed into the machine simultaneously and combined after forming to produce a composite section. Contour roll forming is almost always performed at room temperature; however, some materials, such as certain titanium alloys, must be formed at elevated temperatures. This is done on specially designed machines.

Fig. 1 Setup for contour roll forming of coiled stock (postcut method)

**Influence of Work Metal Composition and Condition.** The effect of work metal formability on procedures and results in contour roll forming is generally the same as it is in other forming methods.

Initial yield strength and rate of strain hardening of the work metal affect contour roll forming. One measure for predicting the formability of a work metal is the Olsen cup test (see the article "Formability Testing of Sheet Metals" in this Volume).

Work metals of equal thickness, with differing compositions, initial yield strengths, and rates of strain hardening, could require alterations in the contour rolling operation. Factors to be considered are: power requirements, number of stations, roll material, lubrication, and speed.

In contour roll forming, it is not uncommon to change the work metal but retain the same shape. In such instances, changes may be necessary in equipment and tooling.

When work metal thickness and tooling remain unchanged, it is seldom a problem to change to a more formable work metal. For example, in changing from low-carbon steel to aluminum, major changes would be unlikely. However, it may be necessary to regrind the finish-station rolls to avoid overbending the section; this would usually be determined by a trial run.

When the change is to a metal of higher strength, one or more changes in procedure may be required to achieve desired results. In forming higher-strength metals such as stainless steels, some overforming is usually required to allow for springback. Residual stress in highly cold-worked metal often causes straightening problems, particularly when forming asymmetrical shapes. A common remedy is to add roll stations to decrease the amount of forming in a given station.

In most instances, difficulty in maintaining size and angle tolerance increases as the yield strength of the work metal increases. Optimum rolling speed decreases as yield strength or hardness increases. For example, in changing from carbon steel to stainless, speed is usually decreased 10 to 25%, mainly to prevent rolls from galling when there is an appreciable amount of roll sweep. One method of combating roll galling without greatly reducing speed is to use extreme-pressure (EP) additives in the lubricant; for extreme conditions, pigmented drawing compounds can be added to the lubricant. The main disadvantage of special lubricants is the difficulty and expense involved in removing them from finished workpieces.

Aluminum bronze rolls are often an advantage in shaping the difficult-to-form metals because they resist galling; however, bronze rolls are softer and wear faster than do tool steel rolls. Rolls made from D2 tool steel, hardened and chromium plated, are usually best for contour roll forming of high-strength metals (see the section "Roll Materials" in this article).

## Process Variables

In contour roll forming, material is progressively formed as it passes from one station to another. The variable parameters in a roll-forming operation include power requirement, forming speed, and type of lubricant. These parameters are determined by width, thickness, and type of material; complexity of the cross section to be formed; coating (if any) on the material; and accuracy required.

**The power required** by a roll-forming machine depends on the torque loss through the drive gearing and the friction between the material and the rolls as the material is being formed. The particular alloy and its thickness must be taken into consideration when looking at the effect of material on power requirements. Generally, contour roll-forming machines have motors ranging from 10 to 50 hp on small machines and from 50 to 125 hp on larger machines.

**Forming Speed.** Speeds used in contour roll forming can range from 0.5 to 245 m/min (1.5 to 800 ft/min), although this speed range represents unusual extremes. Speeds between 25 and 30 m/min (80 and 100 ft/min) are most widely used. One or more of the following can influence optimum forming speed:

- Composition of the work metal
- Yield strength or hardness of the work metal
- Thickness of the work metal
- Severity of the forming operation
- Cutting of finished shapes to length
- Number of roll stations
- Required auxiliary operations
- Use of lubricant (coolant)

Lower speeds in the range indicated previously (near 0.5 m/min, or 1.5 ft/min) are required for contour roll forming titanium into a relatively complex shape. At the other extreme, a speed of 245 m/min (800 ft/min) has been used in production operations in which conditions were nearly ideal, that is, for contour rolling low yield strength metal, such as aluminum or annealed low-carbon steel, in thicknesses less than 0.91 mm (0.0359 in.), in an operation having mild forming severity and requiring cutoff into relatively long lengths (about 25 m, or 80 ft). To use such high speeds effectively, even though forming is not severe, more stations are usually required to minimize the amount of forming in any one station. High forming speed usually precludes auxiliary operations, such as punching, notching, or welding, and requires a flood of lubricant at each station.

The preceding first four factors are closely related and influence permissible forming speed. In addition, one or more of the last four factors may dictate a lower speed regardless of the otherwise permissible speed.

**Lubricants** prevent metal pickup by the rolls (thus improving finish on the work metal and prolonging roll life) and also prevent overheating

of rolls and work metal. When rolls become overheated, their life is shortened. If work metal is overheated, it may warp and require straightening. When lubricants can be tolerated, rolling efficiency is usually increased by their use.

Soluble oils (in a 1-to-12 mixture with water) are the most commonly used lubricants. They are usually applied by a pumping action from a self-contained sump in the machine base through a manifold having flexible tubes and nozzles that direct the fluid to the required locations. Gutters are arranged around the top of the machine to catch the fluid and return it to the sump.

Other lubricants have been used satisfactorily for specific applications. In addition to lubricating and cooling, however, a lubricant must be nontoxic, noncorrosive to the metal being formed (as well as to rolls and other machine components), and removable by available shop cleaning facilities. For instance, some silicone-base fluids are excellent lubricants for roll forming, but they are extremely difficult to remove from metal surfaces. This poses problems in obtaining satisfactory plating or adherence of organic coatings or adhesives. Extreme-pressure lubricants are sometimes used in severe roll forming.

For some applications, no lubricant is permitted (for example, for the forming of painted or otherwise coated metals or for the forming of complex shapes that would entrap lubricants). The result could be a reduction of rolling speed or lower-quality finish, or both. However, in some instances, even though flooding with lubricant cannot be tolerated, other means can be used to supply some lubricant to the rolls. One method is to mount cellulose sponges in constant contact with the rolls and to keep them wetted with lubricant by hand or by drip applicators.

Despite the fact that lubrication is helpful and often necessary in contour rolling, application and subsequent removal of lubricants are significant cost items. When roll forming steel, however, the selection of hot-rolled, pickled, and oiled grades of work metal has often eliminated the need for an additional lubricant. More information on the role of lubrication and the types of lubricants used in sheet forming is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

## Machines

The contour roll-forming machine most commonly used has a number of individual units, each of which is actually a dual-spindle roll-forming machine, mounted on a suitable base-plate to make a multiple-unit machine. The flexibility of this construction permits the user to purchase enough units for immediate needs only. The purchase of additional length of base-plate on the machine allows the addition of units at any time for future needs. Some of these

machines are provided with machined ends on the baseplates, making it possible to couple several machines together, in tandem, to provide additional units as required.

Screws for making vertical adjustments of the top rolls are designed with dials and scales to provide micrometer adjustment and a means of recording the position of the top shaft for each roll pass and each shape being formed. Shaft diameter on most machines ranges from 25 to 102 mm (1 to 4 in.).

Several types of roll-forming machines or roll formers are used. They can be classified according to spindle support, station configuration, and drive system.

**Spindle Support.** Roll-forming machines can be classified according to the method by which the spindles are supported in the unit. Generally, two types exist: inboard or overhung spindle machines and outboard machines.

*Inboard-type machines* (Fig. 2a) have spindle shafts supported on one end that are 25 to 38 mm (1 to 1.5 in.) in diameter and up to 102 mm (4 in.) in length. They are used for forming light-gage moldings, weather strips, and other simple shapes. Material thickness is limited to about 1 mm (0.040 in.), and the top roll shaft is generally geared directly to the bottom shaft. This direct-mesh gearing permits only a small amount of roll redressing (no more than the thickness of the material being formed) on the top and bottom rolls. Tooling changeover is faster on this machine than on the outboard type of machine.

*Outboard-type machines* (Fig. 2b) have housings supporting both ends of the spindle shafts. The outboard housing is generally adjustable along the spindles, permitting shortening of the distance between the supports to accommodate the roll forming of small shapes of heavy-gage material. This adjustment also permits the machine to be used as an inboard type of machine when desired. Outboard machines can be readily designed to accommodate any width of material by making the spindle lengths suit the material width and then mounting the individual units and spindles on a baseplate of suitable width. This type of machine is built with spindle sizes ranging from 38 to 102 mm (1.5 to 4 in.) diameter and with width capacities up to 1830 mm (72 in.).

Generally, for roll-forming material more than 5 mm ( $3/16$  in.) thick, machines are constructed so that both top and bottom shafts can be removed by lifting them vertically from the housings after the housing caps have been removed. This permits rolls to be mounted on the shafts away from the machine, an important consideration when heavy rolls are being handled. This type of machine is built in spindle sizes ranging from 50 to 380 mm (2 to 15 in.) in diameter.

**Station Configuration.** As mentioned previously, a typical contour roll-forming machine consists of several individual forming units mounted on a common baseplate. The manner in which the forming units are mounted determines

to a great extent the type of shapes that are formed on the machine.

*Single-duty machines* are built and designed for a one-purpose profile or for one particular set of roll tooling and are not normally designed for convenient roll changing. This machine is generally used for long production runs, and its cost is low in comparison with the other styles.

*Conventional (standard) machines* are more versatile than single-duty machines because the outboard supports are easily removed. This facilitates roll changes, making conventional machines suitable for a variety of production requirements.

To change the tooling, the top and bottom spindle lock nuts are removed and the outboard

housing is pulled off the spindles. The tooling can then be removed and replaced with the desired profile.

*Side-by-side machines* (Fig. 3) are designed for multiple-profiled tooling and provide the flexibility of having more than one set of roll tooling mounted on the spindle shaft at the same time. Generally, this type of machine is limited to two sets of rolls at a given time, but there can be up to three or four sets of rolls when small profiles are being run in production. Changeover from one production profile to another is accomplished by shifting the machine bed to the desired profile. The main advantages of the side-by-side configuration are low initial investments, fast tooling change, and reduced floor space requirement. Roll wear, however, can create problems because one set cannot be reground without regrinding the others at the same time. Adjusting for material variations can also be a problem.

*The double-high machine* configuration consists of one set of roll tooling mounted on its own roll shafts and housings at one level on the bed frame, and a second complete set of roll tooling and housings mounted at a different level on the same frame. This particular type of machine is used in the metal building industry for forming building panels up to 1520 mm (60 in.) wide.

*The rafted machine* configuration resembles the single-duty and conventional configurations because each configuration has housings and spindle shafts with one particular set of roll tooling mounted on it. However, the rafted configuration has several roll-forming units mounted on rafts or subplates that are removable from the roll-former base. During tool changeover, the individual rafts are removed from the base, and the replacement rafts with the roll-forming units and tooling are installed. On a typical 16-stand roll-forming machine, there are four sets of rafts containing four forming units each.

*Double-head machines* are designed and constructed with two separate sets of housings and roll shafts mounted so that they face one another. Each housing is mounted on an

**Fig. 2** Two basic machine concepts for contour roll forming. (a) Inboard-type machine. (b) Outboard-type machine

**Fig. 3** A side-by-side contour roll-forming machine, which allows forming of several different profiles on the same machine

adjustable plate mechanism to allow the housing to be shifted for a change in overall width while at the same time maintaining the same profile for the edge formation.

This type of machine is very popular in the shelving industry, in which large, flat panels are rolled on a production basis and the panel widths change regularly. A disadvantage of this type of machine is that it does not lend itself to forming the center of the panel. Two of these machines, connected by an automatic transfer mechanism, are used to form the four edges of a shelf; the first machine forms the two long edges, and the second machine forms the two end configurations.

**Drive Systems.** The five basic methods used to drive roll-forming units are chain drive, spur gear drive, worm gear drive, square gearing, and universal drive.

A *chain drive* consists of a sprocket attached to the individual roll-forming unit and connected to the main drive by means of a roller chain. This is accomplished using a continuous roller chain, with one long chain driving each unit, or a shorter chain connected to each individual unit. This drive system is inexpensive and allows flexibility in the construction of the machine.

A *spur gear drive* consists of a continuous train of spur gears mounted at the rear end of each spindle shaft. Idler gears are positioned between each unit to transfer the drive equally to all the units.

A *worm gear drive* is very similar to the spur gear drive. However, instead of using the idler gear to transfer the drive to each unit, an individual worm gearbox is mounted on the bottom spindle of each unit. The worm gearboxes are coupled in line, which permits the machine designer to spread out the horizontal centers of each roll-forming station without being concerned about properly meshing the gear train to the idler gear.

*Square gearing* also incorporates both spur gears and a worm gear. This type of gearing permits a vertical adjustment of the upper spindle and allows use of a wide range of roll diameters.

*Universal drive* eliminates the need for any spur gearing or roller chain and sprocket drives. It consists of a series of worm-driven gear boxes with top and bottom outputs that transfer the power source to the individual shafts through a double-jointed universal coupling. On certain applications, only the bottom spindle is driven. This drive system is generally used with rafted-style machines to permit quick tool changeover. Simplicity of design and minimal maintenance are two important advantages of this drive system.

**Machine Selection.** Several factors must be taken into consideration when selecting a machine to be used in a roll-forming operation. These include load capacity, section size and shape, and roll changeover.

**Load Capacity.** The type and thickness of the material being formed determine to a large extent the load capacity that a given forming machine is required to produce. If material type

and thickness change, it is best to select a machine that can provide the additional capacity.

In forming material up to 1.5 mm (0.060 in.) thick, a machine with 38 mm (1.5 in.) diameter spindles should be used as long as the part is not too wide. A machine with 50 mm (2 in.) diameter spindles can be used for forming material thicknesses up to 2 mm (0.080 in.). As the material thickness increases, the diameter of the spindles must also increase to provide strength to create the pressure required to do the forming. Center distances must be increased as the size of the part shape and the movement of material between forming stations increases. These distances are usually determined by the machine builder.

**Section Size and Shape.** Wide roll-formed sections require wide roll spaces. To support the pressure of the rolls, the spindle shafts must be large enough in diameter to prevent shaft deflection during forming. The distance between the centerline of the bottom spindle and the machine bed determines the maximum roll diameter and hence the maximum section depth.

The more complex the shape of the section being formed, the greater the number of passes (pairs of rolls) required to roll form the section. It is best to select a machine that provides the flexibility of adding or subtracting pairs of rolls in accordance with the part design.

**Roll changeover** can be costly and time consuming because material variations may require different roll pressure settings. When several part configurations must be run on one machine, it is best to select a machine that permits the tooling to be changed quickly. If only two or three profiles are run, the side-by-side and the double-high machines are possible selections; the changeover can be performed quickly without losing valuable production time. Another machine to consider is the rafted machine.

## Auxiliary Equipment

In addition to the machines that do the roll forming, several other pieces of equipment are usually required for production operation. Stock for roll forming is usually received in coils; thus, an electric hoist on an overhead track is needed to lift coils from skids and transfer them to a cradle or reel (another piece of auxiliary equipment). Also, equipment for welding the end of an expended coil to the lead of the next one, an entrance guide, intermediate guides, a straightening device, and cutoff equipment may be needed.

**Stock reels** should be equipped with an expandable arbor to fit the inside diameter of the coil, and with a friction drag. Stock reels incorporating these features are commercially available in a wide range of coil capacities (see the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume).

The friction drag is necessary to prevent the coil stock from overrunning onto the floor in the event of a sudden stoppage of the

roll-forming equipment. In the simplest type of motor-driven stock reel, a dancer arm and roll ride the stock in a loop-detector arrangement, which starts and stops the motor as required, supplying stock at the average rate used by the roll former. Stock speed is matched approximately by adjusting a variable-pitch sheave to prevent too-frequent stopping and starting of the alternating current drive motor. This type of control on the stock reel provides acceptable results for most applications. More elaborate controls can be used, such as a direct current motor drive with feedback control to match stock speed with machine speed. Elaborate controls are expensive and should not be considered unless they are needed to meet special workpiece requirements.

Stock reels are available with a swivel base and two arbors. A coil may be positioned on one arbor while the first coil is being used, thus reducing change time. This arrangement is advantageous when coils are relatively small and production requirements are high because time consumed in changing coils can become a substantial portion of the total production time.

**Welding Equipment.** Thread-up time can be eliminated by manually welding the end of each expended coil to the leading end of the next one. For stock thickness of 1.6 mm ( $1/16$  in.) or more, a semiautomatic welder can be placed in the line. Regardless of the welding method used, any appreciable flash must be removed before the welded joint reaches the first roll station. Provision can be made to remove flash by installing a grinder similar to a band saw blade grinder. More information on combined roll-forming and welding operations is available in the section "Tube and Pipe Rolling" in this article.

**Entrance guides** positioned in front of the first forming station ensure correct alignment of the work metal entering the starting rolls. This is particularly desirable when the part being formed is asymmetrical in the first station because the stock could climb or shift to one side without guides. The simplest form of entrance guide consists of a flat plate with a channel milled to the proper width and depth to accept the strip at its maximum tolerance, plus a simple, removable lid to hold the stock in place. The mounting for this guide should permit adjustment vertically and laterally.

When wide variations in stock width are encountered, a self-centering, parallel-rule entrance guide is preferred. This guide is constructed like a navigator's parallel rule, with the crossbars pivoted and mounted at their centers with a spring, causing the side bars or rules to close on the stock under spring-load.

Stock drags are occasionally used to place a slight tension on the stock and to cause it to feed more uniformly through the first few stations. The simplest form consists of two pieces of hardwood. The stock is clamped between the wooden members, which butt against the entrance guide, thus providing enough friction to keep the stock under tension. The amount of

tension can be regulated by the clamping force on the wooden members.

**Guides between roll stations** facilitate entrance of the partly formed stock into the next station. In theory, if rolls are properly designed, guides between stations are unnecessary because each set of rolls should accept the cross section from the preceding set of rolls. In practice, however, because of such factors as cost, lead time, and availability of space or equipment, the number of roll stations is often fewer than the ideal number; this necessitates more forming in each station than is consistent with the best practice. Therefore, the use of guides between stations helps to compensate for this lack of additional stations and to minimize springback.

Generally, guides between stations are required to contact only the critical points of the work metal, not the entire contour. Regardless of their shape, guides should be designed with removable top portions to facilitate threading.

Various metals may be used for guides, depending on the end-use of the workpiece. For the areas contacting the moving workpiece, hardened steel (usually, case-hardened low-carbon steel) is preferred from the standpoint of guide life. However, when workpiece finish is critical and hardened steel guides are likely to scratch the surface, bronze or aluminum guides are used. For some work, hard chromium plating of guides minimizes damage to workpiece surfaces and still provides acceptable guide life. Guides can be replated when the plating becomes worn.

**Straightening Equipment.** Usually it is necessary to straighten the workpiece after it leaves the final roll station. This is done by standard straightening guides attached to the machine beyond the last set of rolls, or by special devices designed for individual applications.

Straightening guides are usually adjustable vertically and laterally; the most versatile types can be swiveled in either elevation or azimuth and can also be rotated about an axis. Most straighteners employed for contour roll forming are either of the roll type or the shoe type.

A roll straightener consists of multiple rolls (individually adjustable) arranged to contact the stock in selected areas. A shoe straightener consists of one or more shoes, usually made of bronze, properly fitted to the contour and adjustable in at least one direction that will crimp the stock to correct for sweep or twist.

There are also applications in which a sweep (curve) is deliberate and desired. A sweep guide is similar to a straightening guide, and a straightening guide often can be adjusted to give the required sweep in a constant radius. For more detailed information on straightening equipment, see the articles "Straightening of Bars, Shapes, and Long Parts" and "Straightening of Tubing" in this Volume.

**Cutoff Equipment.** Because most contour rolled products are made from coil stock, a system of cutting the formed shapes to length must be provided. There are several types and sizes of flying-shear cutoff machines.

The sliding-die cutoff machine is most commonly used. The action of this machine is similar to that of a punch press, although construction of the machine differs. The flywheel and clutch are placed below the bed, with the ram posts passing through the bed. Gibs are provided in the bed and ram to accept a gibbed die and a punch holder that permits linear movement of the die to match work-metal speed during the cutoff cycle.

## Tooling

Tooling used in roll forming includes the forming rolls and the dies for punching and cutting off the material. Tube mills require some additional tooling to weld, size, and straighten the tubes as they are produced on the machine; the needed tooling is discussed in the section "Tube and Pipe Rolling" in this article.

## Forming Rolls

The rolls are the tools that do the actual forming of the material as it moves through the roll-forming machine. Several factors must be considered when designing the rolls to form a particular part. These include the number of required passes, the material width, the "flower" design, the roll design parameters, and the roll material. *Flower* is the name given to the progressive section contours, starting with the flat material and ending with the desired section profile.

**Number of Passes.** The roll forming of material into a desired final shape is a progressive operation in which small amounts of forming are performed at each pass or pair of rolls. The amount of change of shape or contour in each pass must be restricted so that the required bends can be formed without elongating the material. Too few passes can cause distortion and loss of tolerances; too many passes increase the initial tooling cost.

Generally, the number of passes depends on the properties of the material and the complexity of the shape. Other areas to consider are part width, horizontal center distance between the individual stations, and part tolerances. The number of passes must be increased as the tolerances of the shape become tighter.

**Material.** Material thickness, hardness, and composition all affect the number of passes required to achieve a desired shape. As the thickness of the metal increases, the number of passes required to form the material increases. Steel that has a high yield strength should be overformed approximately  $2^\circ$  and then brought back to finish size on the final pass. Overforming compensates for springback that is encountered when materials having high yield strengths are formed. Material that is coated or that has a polished surface generally requires more passes than does uncoated material. Precut material may also require more passes so that

the rolls can pick up the leading end of each section.

**Shape complexity** is determined by the number of bends and the total number of degrees that the formed part must be bent. It is also influenced by the symmetry of the part design. The forming angle method is a rule of thumb that roll designers use to determine the approximate number of passes.

On simple shapes, a forming angle of  $1$  to  $2^\circ$  is recommended. This forming angle is based on the amount of bending performed for every inch of distance between station centers (horizontal center distances). The minimum forming length for a single bend is determined by multiplying the height of the desired section by the cotangent of the forming angle. This length is then divided by the distance between station centers on a given machine to determine the approximate number of passes. For multiple bends, the number of passes must be determined for each bend and then, after the formation of bends have been combined where possible, the approximate number of passes can be determined.

**Horizontal Center Distance.** If the machine on which the section must be run is predetermined, the specifications and limitations of the machine will have a bearing on the number of passes required. The distance between stations (horizontal center distance) may dictate more stations if that distance is too short. The total distance from flat material to finished section is more critical than the number of stations because undue stresses are created by forming too fast.

**Strip Width.** The width of strip required to produce a given shape is determined by making a large-scale layout, dividing it into its component straight and curved segments, and totaling the developed width along the neutral axis. The outside profile and the neutral axis of each curved segment can usually be treated as circular arcs. Also, for bends having an inside radius of up to about twice the stock thickness in low-carbon steel, the neutral plane or axis is located approximately one-third of the distance from the inside surface to the outside surface at the bend.

**Developed width**, sometimes termed *bend allowance*, is the amount of material required to form a curved section of a particular shape properly. The two methods for calculating developed width described in this section use general equations and can be employed for all shapes. The equations given are applicable when low-carbon steel is formed; for less-formable materials, values should be increased.

**Method One.** Using this method, developed width  $w$  is calculated as:

$$w = r \frac{\alpha}{57.3} \quad (\text{Eq 1})$$

If the inside bend radius is less than two times the material thickness, then:

$$r = r_i + 0.4t \quad (\text{Eq 2})$$

where  $w$  is in millimeters (inches),  $r$  is the bend radius in millimeters (inches),  $\alpha$  is the angle (in degrees) through which the material is bent,  $r_i$  is the inside bend radius in millimeters (inches), and  $t$  is the metal thickness in millimeters (inches).

If the inside bend radius is greater than  $2t$ , then:

$$r = r_i + 0.5t \quad (\text{Eq 3})$$

If the material is bent through a  $90^\circ$  zero radius or a  $180^\circ$  zero radius,  $w$  is  $1/3t$  or  $2/3t$ , respectively.

**Method Two.** Another method used to determine developed width for a roll-formed part is with the empirical equation:

$$w = (t \times p + r_i)0.01745 \alpha \quad (\text{Eq 4})$$

where  $w$  is in millimeters (inches),  $p$  is a bend factor based on the ratio of inside bend radius to material thickness expressed as a percentage, and the other quantities are as previously described.

The bend factor  $p$  is obtained by first dividing the inside bend radius by the material thickness. After this ratio is obtained,  $p$  may be determined using either the nomograph shown in Fig. 4 or the following calculations. For a ratio less than one:

$$p = r_A \times 0.04 + 0.3 \quad (\text{Eq 5})$$

For a ratio greater than one or equal to one:

$$p = (r_A - 1.0)0.6 + 0.34 \quad (\text{Eq 6})$$

where  $r_A$  is the inside bend radius divided by the material thickness,  $r_i/t$ . If  $p$  is calculated to be greater than 45%, the value is 0.45.

**Flower Design.** The development of the flower—the station-by-station overlay of progressive section contours, starting with the flat strip width before forming and ending with the final desired section profile—is the first step in the design of tooling for contour roll forming. The intermediate profiles between flat material and finished profile are graduated at a rate that enables the section to be completed in the fewest number of stations of passes without compromising general roll-forming parameters. The flower graphically shows the number of passes required to roll form the given profile (Fig. 5).

The two prime considerations in designing the flower are: a smooth flow of material from first to last pass and maximum control over fixed dimensions while roll forming. Other factors to be considered include forming position (a section is usually formed in an upward position), vertical reference line with respect to the number and severity of bends, and drive line (the optimal placement in the rolls for equal top and bottom surface speeds).

**Roll Design Parameters.** After the flower is completed to the satisfaction of the designer, rolls may be drawn around each overlay. For small sections, the roll material should contact the section material as much as possible. It is possible, however, to go too far and oversize rolls, thereby creating too much roll contact, which can be detrimental. Each roll pass must

be examined not only by itself but as part of the total job to determine where to make contact with the section material, where to exaggerate pressures or dimensions, where to clear out rolls so that material flows without restriction from one pass to another, and how to accept the section material from the previous configuration.

Rolls are usually made progressively larger in diameter from one pass to the next to permit the surface speed of each succeeding station to increase. The diameter increase is called step-up. The speed differential between passes creates a tension in the section material and eliminates the possibility of an overfeed between passes. Overfeed is created by an excessive amount of work being done in a single pass, which stretches the section material. Normal step-up is approximately 0.8 mm ( $1/32$  in.) per pass on diameter, but it varies depending on the gage of the section and the particular amount of forming being done in those passes.

Rolls may be solid or split (segmented) depending on the complexity of the section. Simple rolls are usually of a one-piece design, but as complexity of the workpiece increases, the use of split rolls should be considered. There are seldom any marked disadvantages in using split rolls, and one or more of the following advantages can often be gained:

- Turning, grinding, or other machining operations are usually easier to perform on the separate sections of split rolls than on one-piece rolls having a complex contour.
- Sections of split rolls are less susceptible to cracking in heat treatment than are single complex rolls.
- Handling problems are simplified, particularly for large roll sections.
- Because sections of rolls subject to excessive wear or breakage can be replaced separately, split rolls can be more economical than one-piece rolls.
- Split rolls permit the use of different roll materials, as needed, for areas of high and low wear.
- Split rolls allow flexibility in making different widths of the same section by the use of spacers or additional roll sections.

**Fig. 4** Nomograph used to determine percentage of material thickness required when calculating bend allowance

- Split rolls allow for minor adjustments that cannot be made with one-piece rolls.

Figure 6 illustrates some of the advantages of split rolls. In Fig. 6(a), the upper roll is composed of five separate sections. In addition to being easier to manufacture, split rolls of this type can accommodate minor adjustments (by shims or similar means) after the initial trial and before the first production run.

Figure 6(b) shows an upper forming roll made up of three sections—a narrow center section flanked by two wider sections. In use, the center section is subjected to a higher rate of wear than are the adjacent flanking sections. The center section of this forming roll can be replaced without changing the flanking sections, or can be made from a more wear-resistant metal.

**Roll Materials.** The materials that are most commonly used for contour rolls are:

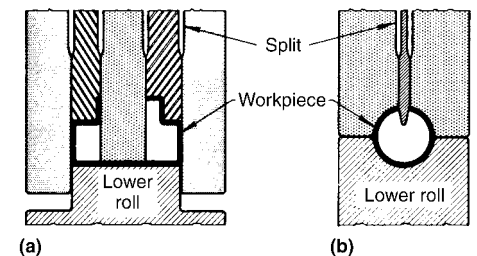

- Low-carbon steel, turned and polished but not hardened
- Gray iron (such as class 30), turned and polished but not hardened
- Low-alloy tool steel (such as O1 or L6), hardened to 60 to 63 HRC and sometimes chromium plated
- High-carbon high-chromium tool steel (such as D2), hardened to 60 to 63 HRC and sometimes chromium plated
- Bronze (usually aluminum bronze)

The quantity of parts to be rolled is usually the major factor in choosing the most appropriate roll material, although other factors, as noted subsequently, also affect selection to some extent, and one or more of them may become definitive in particular applications.

**Short-Run Production.** For rolling small quantities of a specific shape, or when repeat orders are not expected, rolls made of either

**Fig. 5** Development of a flower for design of roll-forming rolls. See text for details.

**Fig. 6** Two types of split rolls used in contour roll forming. (a) Upper roll constructed in five sections allows for minor adjustments. (b) Three-section upper roll allows replacement of center section.

low-carbon steel or gray iron are commonly used. When the work metal is soft and corner radii are generous, low-carbon steel or gray iron rolls can be used for medium- or high-production runs because rolls are easily made from these materials and are not expensive.

**Medium-Run Production.** As the size of the production run increases, rolls made of hardened, ground, polished tool steel, such as O1 or L6, are usually more economical and are widely used.

Not only are these materials relatively inexpensive, they machine more easily than more highly alloyed tool steels and they can be heat treated by simple procedures. Rolls made of these steels can be plated with up to 25  $\mu\text{m}$  (1 mil) of chromium to reduce galling or scratching of the work metal, or to extend tool life between grinds by decreasing roll wear or minimizing corrosion or pitting.

**Long-Run Production.** For long production runs (>5 million ft) or continuous high production, it is usually more economical to make rolls from one of the high-carbon high-chromium tool steels, such as D2. These highly alloyed grades cost nearly twice as much as O1, are more difficult to machine and grind, and require more complex heat treatments, but because of their longer life between regrinds, are usually more economical for long runs.

**Factors Other Than Quantity.** Three other conditions, under any one of which rolls made of steel such as D2 are often preferred (quantity becoming a secondary consideration), are: excessively hard work metal (low formability), excessively sharp radii or other severe forming conditions, and work metal surfaces that are abrasive (such as unpickled hot-rolled steel) and cause excessive roll wear. Rolls made of highly alloyed tool steel may also be plated with chromium for the reasons mentioned in the section "Medium-Run Production."

**Special Finish Requirements.** In many applications, such as the rolling of light-gage stainless steel, aluminum alloys, or coated stock, preservation of surface finish is of primary concern. With these work metals, softer rolls are used to avoid damaging the work metal surface, even though there may be a substantial reduction in roll life.

As workpiece surface finish requirements become more rigorous, softer rolls are required. Rolls made of bronze are often used. In some applications, the plating of hardened steel rolls is sufficient to prevent the marring of work metal surface finish.

## Tube and Pipe Rolling

Welded-seam pipe and tube are contour roll formed by three methods: edge forming, center forming, and true-radius forming. Edge and center forming (Fig. 7a and b) require complete sets of rolls for each size of tube because the stations that precede welding have the final radii in the roll contours. In true-radius forming

(Fig. 7c), the breakdown rolls can be used for a range of sizes, which reduces tooling cost and setup time.

For all three methods of producing welded tubing, the forming rolls are termed as breakdown and finishing rolls. Breakdown is usually accomplished in the first three or four roll stations, as indicated in Fig. 7.

Optimum distance between the edges of the stock in the final finishing station (stations 6, 7, and 5 in Fig. 7a, b, and c, respectively) is affected by the method of welding and tube size. For resistance welding, however, the following relations of tube size to distance are typical:

Tube diameter		Distance	
mm	in.	mm	in.
9.5	3/8	1.57	0.062
25	1	3.15	0.124
51	2	4.37	0.172
102	4	6.35	0.250

Machine size is determined by material thickness and tubing size. Large pipe sometimes requires a machine having spindles 305 to 355 mm (12 to 14 in.) in diameter.

Speed of production is controlled by thickness and type of work metal. Aluminum can be formed and welded as fast as 75 m/min (250 ft/min), whereas titanium tubing is produced at a rate of only 455 mm/min (18 in./min). The welding operation is often the main limitation on the speed at which tubing can be produced by roll forming.

Soluble oils are the most practical lubricant for forming tube and should be used to prevent galling. A mixture of 25 to 40 parts water to 1 part oil is commonly used.

Long roll life can be expected in producing round tubing. Three to four million feet between regrinds is considered normal.

Lock-seam tube (Fig. 7d) has two edges folded over to form a lock. Production of lock-seam tubing is restricted to relatively thin material (usually less than 0.91 mm, or 0.0359 in.)

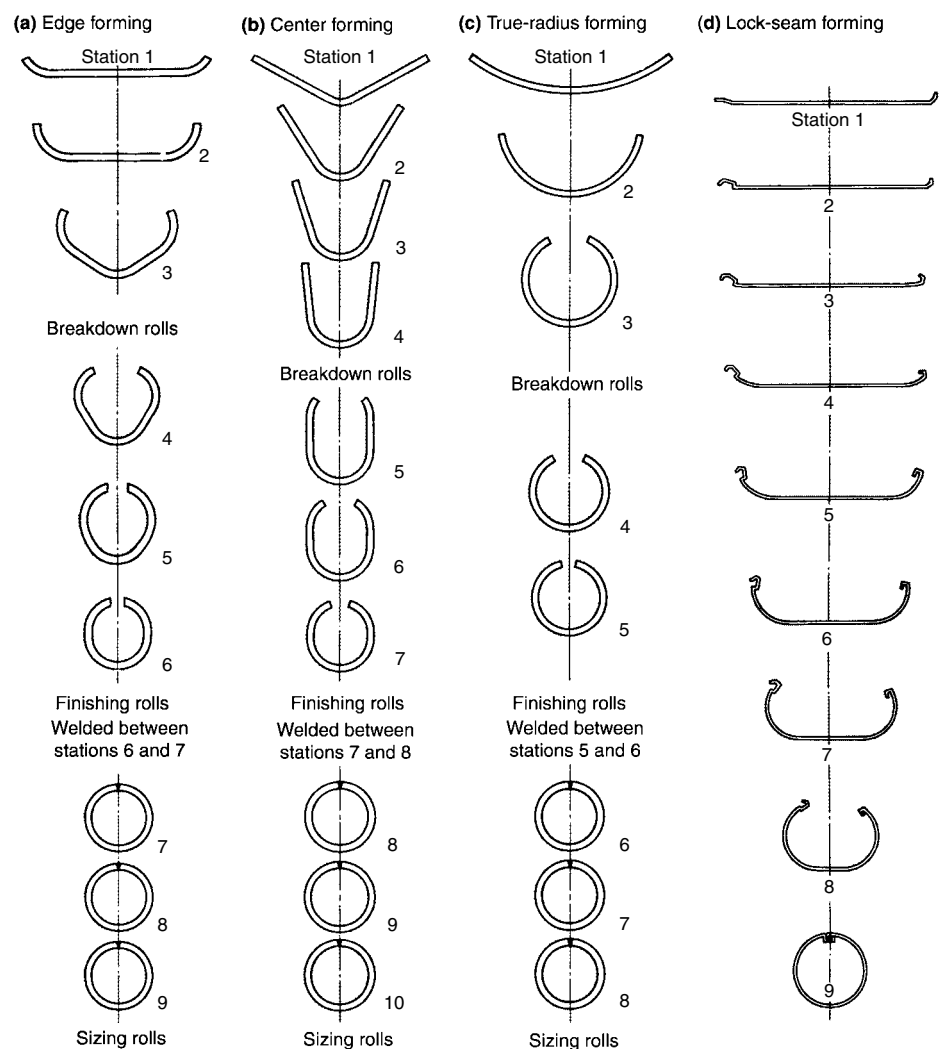

Fig. 7 Typical sequences for forming round pipes and tubes. (a to c) With a butt-welded longitudinal seam. (d) With a lock-seam joint.

because heavier stock is too difficult to lock. The lock-seam method is used extensively for thicknesses that are impractical for welding because they are too thin. Maximum thickness is also restricted by tube diameter. As a general rule, stock thickness should not be greater than 3% of the tube diameter. For instance, 0.76 mm (0.030 in.) is about the maximum thickness of strip that should be used to produce 25 mm (1 in.) outside diameter (OD) tubing.

Minimum width of the lock should be five times the material thickness. The lock-seam method is also applicable to square tubing.

The various stages of lock-seam forming are shown in Fig. 7(d). Idlers are used between stations 4 to 8. Between stations 8 and 9, a lock housing unit that is equivalent to two stations is used. Both side rolls and vertical rolls are used in the locking stand, the main purpose of which is to lock the two edges of work metal in the groove. A mandrel is placed inside the tube to help form the small lock. This mandrel is in the locking stand and extends beyond station 9. In the last station, two small rolls ride opposite each other on the mandrel, pushing the work metal to form a tight lock between the top and bottom rolls in station 9. It is necessary to have close control over the stock thickness, because a 0.025 mm (0.001 in.) difference in thickness will result in a difference of about 0.13 mm (0.005 in.) in the outside diameter of the tube.

## Roll Design for Tube Rolling

A number of designs and methods are used for forming strip into a tubular shape suitable for welding, with many factors involved in choosing the proper roll design for producing a particular tube.

Figure 8 illustrates one of the most commonly used designs for rolls used for forming the tube before welding. The rolls are designed with a single forming radius in each roll pass. This radius decreases progressively in each roll pass until the final pass. The radius of the final roll pass is slightly larger than the finished tube size to permit the insertion of a thin fin in the top roll to act as a guide for the two edges of the material. Generally, for the last two or three roll passes, there are fin rolls in the top rolls to guide the two edges of the strip, prevent twisting of the tube, and ensure accurate positioning of the seam entering the welder. Idler rolls mounted on vertical spindles between the driven-roll passes are positioned to prevent excessive rubbing and scuffing of the side of the tube as it passes through the succeeding driven-roll pass. The number of driven-roll passes can vary, increasing as the tube diameter increases, but five driven passes are considered a minimum.

For forming tube with either a very thin wall or a very thick wall (<3% of the OD of the tube, or >10% of the OD of the tube), a modification of the design shown in Fig. 8 is used. This modification is obtained by forming the

portion of the strip adjacent to the edges to the finished radius of the tube in the first forming pass, instead of depending on the fin passes to finish form at the edges. This finished form at the edges of the strip helps to prevent buckles and waviness at the edges of the strip as it passes through the forming rolls when very thin material is being formed, and it helps to avoid the necessity of extreme pressures at the fin rolls when extra-heavy-gage material is being formed. Figure 9 illustrates the first four sets of rolls used in this method of tube forming. The remaining rolls are similar to those shown in Fig. 8.

Fig. 8 Typical sequences for roll forming tubing from strip material.

In forming material of high tensile strength when springback of the metal is a factor, a third method of forming is sometimes used. In this design, a part of the strip is formed to the finished tube radius in each roll pass, progressing from the two edges toward the middle until the fin passes are reached. The forming radius on the rolls is less than the finished radius of the tube to compensate for the springback of the material.

## Welding

Seam welding of pipe and tubing is generally performed using either low-frequency rotary-electrode welding or high-frequency welding; laser welding is beginning to be used (see the section "Laser Welding"). High-frequency

Fig. 9 First group of rolls for forming tubing from thin strip material from the edges inward.

resistance welding and high-frequency induction welding for tube diameters less than 25 mm (1 in.) (Fig. 10) have become more predominant in recent years in the production of welded tubing (see the article "High Frequency Welding" in *Welding, Brazing, and Soldering*, Volume 6 of *ASM Handbook*). With rotary-electrode welding, the maximum wall thickness that is economically feasible is 4.5 mm (0.180 in.). Using high-frequency welders, wall thicknesses as thick as 19 mm (0.75 in.) and as thin as 0.13 mm (0.005 in.) are obtainable. After the welding operation, the piece is usually sized and then straightened before being cut to length.

**Laser Welding.** Powerful carbon dioxide ( $\text{CO}_2$ ) lasers also have been used to make longitudinal welds in contour roll-formed stainless steel tube. In this process autogenous (no filler metal) welds were made in types 304 and 430 stainless steel tubes using a 5 kW  $\text{CO}_2$  laser at a speed of 5 m/min (16.5 ft/min). Tubes had a wall thickness of 1.5 mm (0.060 in.) and a diameter of 48.5 mm (1.91 in.). Laser welding resulted in joints that were tougher and more ductile than joints made by other welding processes.

**Sizing and Straightening.** Tube and pipe are welded to an OD slightly larger than the finished diameter. The sizing rolls can then produce round, accurately dimensioned, straight, finished tube. A typical set of sizing and straightening rolls consists of three driven-roll

passes, vertically mounted idler rolls between each driven pass, and finally, a set of idle cluster rolls that are adjustable both vertically and horizontally for final straightening of the tube. The roll radius for each driven roll successively decreases to size the tube down to its proper diameter.

## Reshaping of Round Tubing

Several cross sections that can be feasibly produced by reshaping round tubing are shown in Fig. 11. Reshaping can be done either continuously in sequence with the production of round tubing or in a separate operation.

On square and rectangular tubing, the flatness of the sides will vary with work metal thickness and hardness. On light gages and in the harder tempers, springback results in a crown effect on the sides. This condition can be corrected by overforming in the final station. In forming rectangles, the longer sides may become convex, and the short sides may become concave. Flatness can be controlled to a minor extent by roll adjustments in the finish station, but a major correction must be made by using concave or convex contours in final Turk's-head rolls.

Rolling speeds used in reshaping tubing of light-gage metal are often equal to those used in producing the basic round tube. For reshaping heavier-gage tubing (for example, over 0.89 mm, or 0.035 in.), speed should be reduced by as much as 25% of that used for forming the round tube, depending mainly on the capacity of the equipment.

**Tooling requirements** for reshaping round tubing vary with the gage, size, and complexity of the final shape. It is often possible to form simple squares from thin-gage round tubing in one roll station and one Turk's-head station. However, as stock thickness or complexity of shape, or both, increase, more stations are required.

## Tolerances

Cross-sectional tolerances on part dimensions are a result of variations in material width and thickness, physical properties of the material, quality of the tooling, conditions of the machine, and operator skill. Dimensional cross-sectional tolerances of  $\pm 0.25$  to  $\pm 0.78$  mm (0.010 to 0.030 in.) and angular tolerances of  $\pm 1^\circ$  are common. Tolerances are slightly greater when wide building panels and deep sections are being formed. If a closer tolerance is required, material with a controlled-thickness tolerance of  $\pm 0.05$  mm (0.002 in.) should be used.

Length tolerances are dependent on material thickness, part length, line speed, equipment quality and condition, and type of measuring and cutoff system used. For thin material (0.38 to 0.64 mm, or 0.015 to 0.025 in., thick), tolerances of  $\pm 0.51$  to  $\pm 2.36$  mm (0.020 to 0.093 in.) are obtainable. For material more than 0.64 mm (0.025 in.) thick, tolerances of  $\pm 0.38$  to  $\pm 1.52$  mm (0.015 to 0.060 in.) are obtainable. The minimum tolerances are based on part lengths up to 915 mm (36 in.), and the maximum tolerances are based on lengths up to 3.66 m (12 ft). Tolerances would generally be greater on parts longer than those specified.

In roll forming, it is generally advisable to order the material to be formed with somewhat tighter than commercial quality tolerances. If this is done, a great many dimensional problems can be eliminated. Failure to consider material quality results in needless problems and frustrations.

## Straightness

In addition to cross-sectional, angular, and length tolerances, another tolerance to consider is the straightness of the material and the formed section. Some of the parameters that determine straightness include camber, curve or sweep, bow, and twist. The terms camber, curve, and bow are often used synonymously when describing straightness. The horizontal and vertical planes of the formed part are determined by the position in which the part is formed.

**Camber** (Fig. 12a) is the deviation of a side edge from a straight line. Measured prior to roll forming, the maximum allowable camber is 3.2 mm/m ( $3/8$  in. in 10 ft.). Excessive camber contributes to curve, bow, and twist in the finished part.

**Curve or sweep** (Fig. 12b) is the deviation from a straight line in the horizontal plane

**Fig. 10** Two methods of high-frequency welding of longitudinal seams in tubing. (a) Sliding contacts introduce current to the tube edges. (b) Multiturn induction coil induces current to the tube edges.

**Fig. 11** Cross sections showing typical contours that can be produced by reshaping welded or lock-seam round tubing. In addition to these contours, square, triangular, and rectangular shapes can be formed from round tubing in one or more roll stations. Dimensions given in inches

measured after the part has formed. The curve in a formed part can be held to within  $\pm 1$  mm/m ( $\pm 1/8$  in. in 10 ft). Curve or sweep can result from incorrect horizontal roll alignment and uneven forming pressure in a pair of rolls.

**Bow** (Fig. 12c) is the deviation from a straight line in the vertical plane and can be either cross bow or longitudinal bow. Bow results from uneven vertical gaps on symmetrical sections and from uneven forming areas on unsymmetrical sections. Generally, bow can be held to within  $\pm 1$  mm/m ( $\pm 1/8$  in. in 10 ft).

**Twist** in a formed part resembles a corkscrew effect and often results from excessive forming pressure. Twist is generally held to less than  $5^\circ$  in 3 m (10 ft).

## Quality and Accuracy

Two factors that can affect the quality and accuracy of a roll-formed section are springback and end flare.

**Springback** is a distortion that becomes evident after the straining of the part has been discontinued. The amount of springback varies with different metals properties such as yield and elastic modulus. Springback can be compensated for in the tool design by overforming. Overforming forms the material past its expected final shape.

**End flare** is the distortion that appears at the ends of a roll-formed part. The internal stresses incurred in roll forming are much more complex than in other types of bending. These stresses are usually higher in the edges of the material being formed and are released when the part is cut off.

**Control of End Flare.** End flare occurs to some degree in nearly all roll-formed shapes. It can extend back from the end as little as 50 or 75 mm (2 or 3 in.) or as much as 305 mm (12 in.). End flare can range from a few thousandths of an inch (this small amount is usually ignored) to 12.7 mm ( $1/2$  in.) or more. The possibilities for flare can pose difficult problems. Both ends may flare outward, or one end may flare outward and the other inward. Excessive flare is caused by hard work metal, workpiece shape, too few roll stations, unsuitable roll design, or a combination of all of these.

There are several means of keeping end flare within acceptable limits. Replacing a hard work metal with one that is more formable will lessen, but not always eliminate, end flare. Minor changes in shape or design of the workpiece are often feasible and should be considered when end flare is a problem. It is much better to recognize the possibility of excessive flare before designing the rolls than to attempt correction after the rolls are made. The best way to minimize end flare is to provide enough roll stations to prevent the sides or edges of the work metal strip from elongating.

## Surface Finish

Contour roll forming seldom improves the initial finish of the work metal. One exception is the roll forming of unpickled hot-finished steel, from which much scale is removed. It is usually possible to preserve the existing finish on uniform areas of the work metal. Sheet and strip ranging from unpickled hot-rolled steel to highly polished stainless steel are contour roll formed with a minimum of damage to the surface finish. In addition, work metals having almost every known type of coating are contour roll formed in high production with no damage to the coatings.

This does not mean that no damage to the work metal will occur if the specific applications are not carefully considered in planning the processing technique. In addition to normal

precautionary measures, such as keeping the work metal clean before rolling and maintaining the equipment properly, one or more of the following must be considered and possibly adjusted when minimum damage to the surface finish is a primary requirement:

- Roll design or number of rolls in a given station
- Number of stations
- Roll material and finish
- Lubricant
- Rolling speed

As severity of forming increases, the possibility of damage to the work metal surface increases and may require alteration of the rolls within a station. For example, in forming deep channels, the shape can be produced using top and bottom rolls. Side rolls can be added to improve dimensional tolerance. When maintenance of surface finish is a problem, the use of side rolls is helpful because it minimizes roll sweep, which is inevitable when the shape is produced solely by top and bottom rolls. Excessive roll sweep is likely to damage both the work metal and the rolls.

Although sliding friction caused by roll sweep may damage surface finish, there is even greater likelihood of damage from excessive forming pressure in a given roll station. Therefore, as severity of forming increases, the possibility of damage to the work metal finish can be lessened by adding stations, thus decreasing the amount of forming done by a given set of rolls and reducing forming pressures.

Roll material and roll finish also contribute to the surface finish obtained in contour roll forming. Chromium-plated steel rolls or aluminum bronze rolls are best for preserving work metal finish.

Lubrication is preferred in contour roll forming and has a significant effect on work metal finish. When lubricants cannot be tolerated, as in the roll forming of coated metals, more attention must be given to roll design, additional stations, roll materials, and possibly lower rolling speeds than would be used if copious amounts of lubricant were permitted.

Each metal presents a different problem in maintaining surface finish.

**Hot-rolled unpickled steel** seldom offers any problem in maintaining surface finish. Rolling removes much of the scale and usually improves the finish, provided a flood of lubricant is used to flush away the scale. Otherwise, this scale will be trapped between work metal and rolls, resulting in damage to both surfaces. Rolls made from abrasion-resistant tool steel such as D2 are especially recommended for roll forming of hot-rolled unpickled steel.

**Cold-finished carbon steel, aluminum, and brass** are usually rolled with a minimum of damage to work metal finish. One or more of the foregoing conditions may require special attention, depending mainly on severity of forming. A flood of lubricant is desirable in roll forming cold-finished metals.

**Highly polished stainless steel or aluminum** can also be contour roll formed without damage to surfaces. However, each step of the procedure becomes more critical than is the case with roll forming lower-quality finishes. Greater attention must be given to roll design, fitting, and maintenance. Chromium-plated rolls are usually preferred when work metal finishes are critical. Maximum cleanliness in all phases of the operation (including the use of freshly cleaned work metal) is mandatory for achieving desired results. Special lubricants are preferred for roll forming stainless steel and may be essential when forming is severe and quality of finish is critical.

**Galvanized Steel.** Success in roll forming hot dip galvanized steel depends mainly on the quality of the zinc coating, maintenance of the rolls, and lubrication. Inferior galvanizing or severe bends, or both, cause the coating to loosen and stick to the rolls. Wipers that contact the working surfaces of the rolls will aid in preventing surface damage. Chromium-plated rolls are also helpful in minimizing damage to galvanized work metal.

**Precoated metals** (vinyl and other organic coatings) must be rolled without lubricant and sometimes pose problems, although by paying

careful attention to the conditions listed previously, precoated metals can be contour roll formed without damage to the coating surface. One of the most common applications is the forming of aluminum siding for buildings. Complete preservation of finish depends mainly on severity of forming. Sometimes it is necessary to increase radii if the particular operation is to be successful.

**Embossed metals** are also roll formed without lubricants. Shapes are designed to avoid excessive forming pressure, and bend radii not less than twice the metal thickness are used to prevent distortion of the embossing. Forming of aluminum eaves troughs is an example of this operation.

### Use of Computers

Computers are becoming an important aid in the design of roll-forming tooling. Consistency, accuracy, and speed enable the designer to determine the optimal design for each roll pass in less time than is required when the calculations are performed by hand. The capability to display the profile of the part enables the designer to see how the material flows through each pass. This

profile enables the designer to determine whether too much work is being performed at a particular pass.

The numerical information compiled by the computer can be employed in numerically controlled machining operations to ensure that rolls are accurately produced. The computer also aids in the setup of the rolls on the machine by specifying the size and locations of the required shims and spacers. All this information and data can be stored for future use and reproduced whenever necessary.

To design the rolls, information about the roll forming machine, the cross section of the final shape, and the initial forming sequence are entered in the computer program. The computer numerically defines the coordinates of each corner and displays on the computer terminal the profile of the part at each pass as well as various perspectives of the flower diagram. Input changes can be made to vary the material flow through the roll forming machine so that optimum flow is achieved. Computer output includes flower diagrams, drawings of the cross-sectional shape, drawings of the rolls, and tabular data defining the material and rolls. A computer can also produce the tapes used in the manufacturing of the rolls on numerically controlled machines.

# High-Velocity Metal Forming

Glenn S. Daehn, The Ohio State University

HAMMERS were the first tool used to shape billets into useful shapes, but fixed tools, such as stamping dies, became the standard for metal forming during the industrial revolution. Indeed, fixed tools are highly productive, with forces and displacements remotely controlled. However, fixed tools do not offer the local control that was provided by hammer forming. Even today, difficult components in prototype production and aerospace manufacture are commonly produced with the aid of manually operated hammers. High-velocity metal forming techniques are more akin to hammers than presswork, because the impulse is controlled rather than forces or displacements. Also like hammer work, when properly implemented, one can control the spatial distribution of the impulse.

High-velocity forming methods include techniques such as explosive forming and electromagnetic forming. These techniques are distinct from most other metal forming methods in that the explosive or electromagnetic force first accelerates the workpiece to a high velocity, and the kinetic energy of the workpiece is significant. The sheet metal workpiece then changes shape, either as it strikes a die or as it is decelerated by plastic deformation. These methods generally provide robust methods of performing metal forming operations that are quite difficult conventionally. Although these methods have been known for over 100 years and saw significant development (particularly in the 1960s), these methods have not been developed or documented so that they can be routinely used to their potential. However, because these methods work well on even hard-to-form materials, and because manufacturing systems are generally very simple and can be established quickly, there is a recent resurgence in interest in these methods.

This article first provides some general background and emphasis on the traits that are common to high-velocity forming operations (considered here to be operations where the workpiece velocity is above approximately 50 m/s, or 165 ft/s). This overview includes a description of general principles on how metal forming is accomplished and analyzed when inertial forces are large. Second, the principal methods of high-velocity forming are described. This includes the methods of explosive forming,

electrohydraulic forming, and electromagnetic forming. These are all similar in the respect that the workpiece is given kinetic energy early in the process and where forming is largely inertial because kinetic energy is dissipated as plastic deformation. For each of the forming methods, the physics is quite different in determining what the as-launched velocity profile of the workpiece will be. Finally, this article gives examples showing how these techniques can be practically applied. The article concludes with some comments on the status and development potential for this technology.

## Background

High-velocity forming methods were discovered in the late 1800s and saw some application in forming thick plates in the 1930s. Between approximately 1950 and the early 1970s, the United States government funded numerous studies on the development and application of high-velocity forming. The U.S. Defense Advanced Research Projects Agency (DARPA) invested heavily in explosive forming technology in the mid-1960s. DARPA (Ref 1) cites explosive forming as “a cost-effective process for forming a variety of metals and alloys that results in remarkably high reproducibility (~0.5%) for complex, large metal structures. Used extensively in Department of Defense projects, the applications include making afterburner rings for the SR-71, jet engine diffusers, Titan ‘manhole’ covers, rocket engine seals, P-3 Orion aircraft skin, tactical missile domes, jet engine sound suppressors, and heat shields for turbine engines.” Also in the same period, significant research investments were made in the allied technologies of electromagnetic forming and electrohydraulic forming. These methods are explained later and are based on storing the forming energy in a capacitor bank instead of as chemical energy. Electrohydraulic forming is, in operation, quite similar to explosive forming but limited to lower energies. Electromagnetic forming is only directly applicable to materials with high electrical conductivity, and this has been well developed as an assembly technique. Explosive, electrohydraulic, and electro-

magnetic forming have all seen continued use since their development in the 1960s. However, there has been only sporadic research or development in these areas since the early 1970s. It is rather unfortunate that while the old literature shows that these techniques have significant potential, in many cases the information available is not detailed enough to design new processes.

## *Fundamentals of High-Velocity Deformation*

High-velocity forming is characterized by first imparting a high velocity to a workpiece, and this energy is turned to plastic deformation by constraint of the part or impact with a die. The velocity distribution for the part is determined by the pressure distribution or developed from the explosive, electromagnetic pressure distribution (determined by coil shape) or shock wave profile. Changing the amount of energy available will change the absolute values of the velocities. Once the velocity is imparted, the shape can be developed either by free forming or die forming. Examples of these are shown in Fig. 1. Free forming can be used to create bulges that take on roughly spherical section geometries. Because there is no direct die contact, these methods do not have great dimensional precision. This method has been used, for example, to form the ends of pressure vessels from a monolithic metal plate. When better dimensional precision is required, forming into a die is used. In die forming, one must often pull a rough vacuum between the sheet and die before forming, or the rapidly compressed air will cause the part to rebound. An appropriate array of holes can also permit air movement in forming. Also, if the workpiece strikes the die at too high a velocity, it may rebound (i.e., bounce off). This will also impair dimensional tolerance.

Note that these techniques are distinctly different from conventional stamping in that only a single tool is typically used. In this respect, the techniques can be compared to methods such as superplastic forming or hydroforming. However, high-velocity techniques can have significant advantages over both. Unlike superplastic forming, the process is typically carried out at

room temperature, and it is a robust forming technique for almost any alloy, whereas superplastic forming can only be applied to a very limited set of materials at low strain rates. In comparison to hydroforming, because large forces and pressures in high-velocity forming only act for a short period of time, the inertia of tools is often more than sufficient to constrain them, and very light tooling systems can be used. This avoids the high die, equipment, and setup cost associated with hydroforming. However, high-velocity forming can be well suited to forming large and complex parts, resulting in large cost savings versus assemblies.

**Basic Elements.** There are a number of basic technical elements that distinguish high-velocity forming from conventional stamping. These must be appreciated if the techniques are to be used effectively. Important issues include understanding how to account for inertia, impact, and the new loading modes available. These are described briefly, and their direct application to metal forming is shown later.

**Inertia—Resistance to Further Velocity Change.** Newton's law,  $\vec{F} = m \vec{a}$ , can be summarized as saying a body (or a material point in a deforming body) prefers to maintain its present velocity. If one piece of material is to change its velocity by some amount, the force required to do so is inversely proportional to the time available to effect that change. That is to say, after

a workpiece has been launched in short time periods (or at high velocity), bodies very much prefer to maintain their launch velocity profile. A basic difference between conventional forming and high-velocity forming is that in the former, use inertial forces can be ignored, while they are dominant in the latter case. As is described later, this has important implications to both formability and wrinkling.

**Impact—High Pressures Easily Created.** Something fairly unique to high-velocity forming is that very high pressures are created when two solid bodies impact with significant velocity. A detailed understanding of this requires the study of wave behavior in solids and is beyond the scope of this article, but Ref 3 gives an excellent treatment of the background. One useful result is the impact pressure,  $P$ , that is developed when two semi-infinite elastic bodies, labeled "1" and "2," collide at an impact velocity,  $V_i$ :

$$P = \frac{\rho_1 \rho_2 C_1 C_2}{\rho_1 C_1 + \rho_2 C_2} V_i \quad (\text{Eq 1})$$

where for each material,  $\rho$  represents density, and  $C$  is the longitudinal wave speed, which can be expressed as:

$$C = \sqrt{\frac{3K(1-\nu)}{\rho(1+\nu)}} \quad (\text{Eq 2})$$

where  $K$  represents bulk modulus, and  $\nu$  is Poisson's ratio. Longitudinal wave speeds are on the order of approximately 7000 m/s (23,000 ft/s) for most structural metals. Equation 1 shows that for aluminum-steel and steel-steel couples, impact pressures of 500 MPa (73 ksi) and 1.4 GPa ( $0.20 \times 10^6$  psi) are generated for a 50 m/s (165 ft/s) impact. This analysis shows that it is very easy to develop pressures large enough to produce plastic deformation at the interface. More sophisticated analyses are required to study the deformation of the interface once plastic deformation takes place. However, it is clear that even modest impact speeds can produce significant plastic deformation at the interface. Such pressures can be used to put great surface detail into material or to perform embossing or coining-like operations. Also, explosives themselves can provide enormous pressures that can be used practically. Common explosives can produce pressures on the order of 20 GPa ( $3 \times 10^6$  psi). Here, impact is not required to generate huge pressures.

**Changes in Constitutive Behavior.** High-velocity deformation may or may not involve high strain rates. It is well known that the fundamental constitutive behavior (stress, strain, strain-rate relations) for most metals changes qualitatively at strain rates above approximately  $10^4 \text{ s}^{-1}$ . Above these strain rates, the apparent strain-rate sensitivity of the material increases markedly. This may actually be related to the increase of the material rate of strain hardening instead. However, many high-velocity forming operations do not result in high strain-rate effects. For example, if one is to consider tube

expansion at 200 m/s (655 ft/s) a tube diameter of 4 cm (1.6 in.) will sustain a strain rate of  $10^4 \text{ s}^{-1}$  in the hoop direction. However, a 1 m (3.3 ft) diameter tube will only have a hoop strain rate of  $400 \text{ s}^{-1}$  at the same expansion velocity. Thus, while these changes in constitutive behavior can be important, they are not universal to all forming operations, even if they are carried out at high velocity.

**New Loading Modes Possible.** The methods used to impart velocity to a sheet are quite distinct from those traditionally used, in that launch does not usually involve contact with a hard punch or tool. Specifically, in the case of electromagnetic forming, body forces are produced by the interactions of magnetic fields without any contact. As is shown later, these forming devices can be integrated with conventional tooling, greatly expanding the capabilities of traditional stamping. Also, these unusual modes of imparting energy to a body, along with the short loading duration, offer the ability to use very lightweight and simple forming systems.

## Characteristics of High-Velocity Metal Forming

The basic elements (large inertial forces, impact forces, changes in constitutive behavior, and new loading modes) offer many useful attributes to metal forming. These attributes can be designed into a number of new or enhanced manufacturing processes. The characteristics of these elements are described in this section, and examples follow at the end of this article.

**Improved Formability.** In conventional stamping, formability, as described by the set of available strain states that can be attained, is described by the forming limit diagram (see the article "Formability Testing of Sheet Metals" in this Volume). This forming limit diagram does not include inertial effects and therefore cannot describe formability in high-velocity forming; inertia and specific boundary conditions can help or hurt formability. Different issues control formability, and the forming limit diagram no longer approximately describes formability, as a few brief examples illustrate.

First, consider a simple tensile test. As is standard, one end of the sample is held fixed and the other is moved with some velocity. W.W. Wood (Ref 4) carried out a series of experiments where the end velocity was varied by both conventional testing and impact experiments. He studied several materials and consistently found that there were three distinct regions in the ductility-velocity plot. Below a first critical velocity, strain to failure was independent of endpoint velocity. Between a first and second critical velocity, strain to failure was significantly increased, and beyond this second critical velocity, strain to failure dropped to nearly zero. These results are summarized in Fig. 2.

Below the first critical velocity, the sample behaves in the ordinary way, where ductility is not a strong function of strain rate. Above the

**Fig. 1** Example of (a) free forming and (b) die forming as accomplished with explosive forming. Source: Ref 2

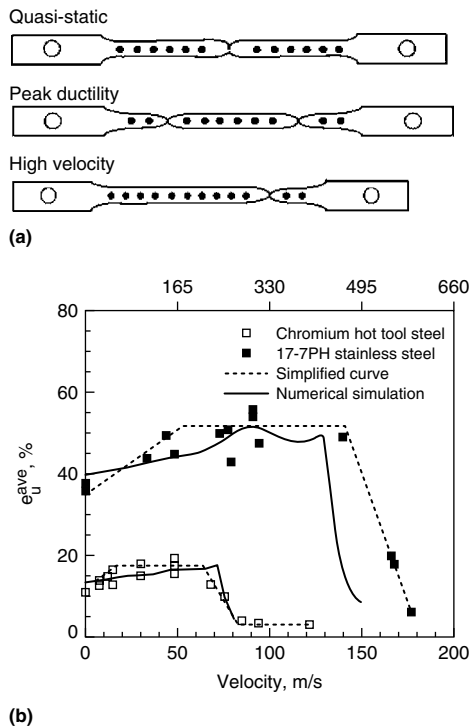

second critical velocity, the velocity imposed to the endpoint is greater than the effective plastic wave speed. Therefore, significant deformation is deposited in the driven end of the sample before the stress is fully transmitted to the fixed end of the sample. This results in the sample pinching off near the driven end. This second critical velocity is known as the von Karman velocity, and this is related to the plastic wave speed in the material (which is much lower than the elastic wave speed, because both are related to the slope of the stress-strain curve in the respective elastic and plastic regimes). This second critical velocity is between approximately 30 and 150 m/s (100 and 490 ft/s) for most important engineering alloys. Between these two critical velocities, a period of enhanced ductility is expected and observed.

The reduced ductility at high velocities observed in uniaxial tensile deformation can be attributed to the strongly nonuniform velocity distribution initially delivered to the sample. Initially, one end moves at a high velocity while the other is fixed. This problem can be addressed by using a different launch profile or different boundary conditions. In Fig. 3, electromagnetic forming was used to launch an aluminum ring in an axisymmetric radially outward manner. Now, if only inertial forces were active, every material point along the ring would move along the radial outward path that it was launched along. However, in simple tension, the usual instability present in tensile test eventually takes over, and

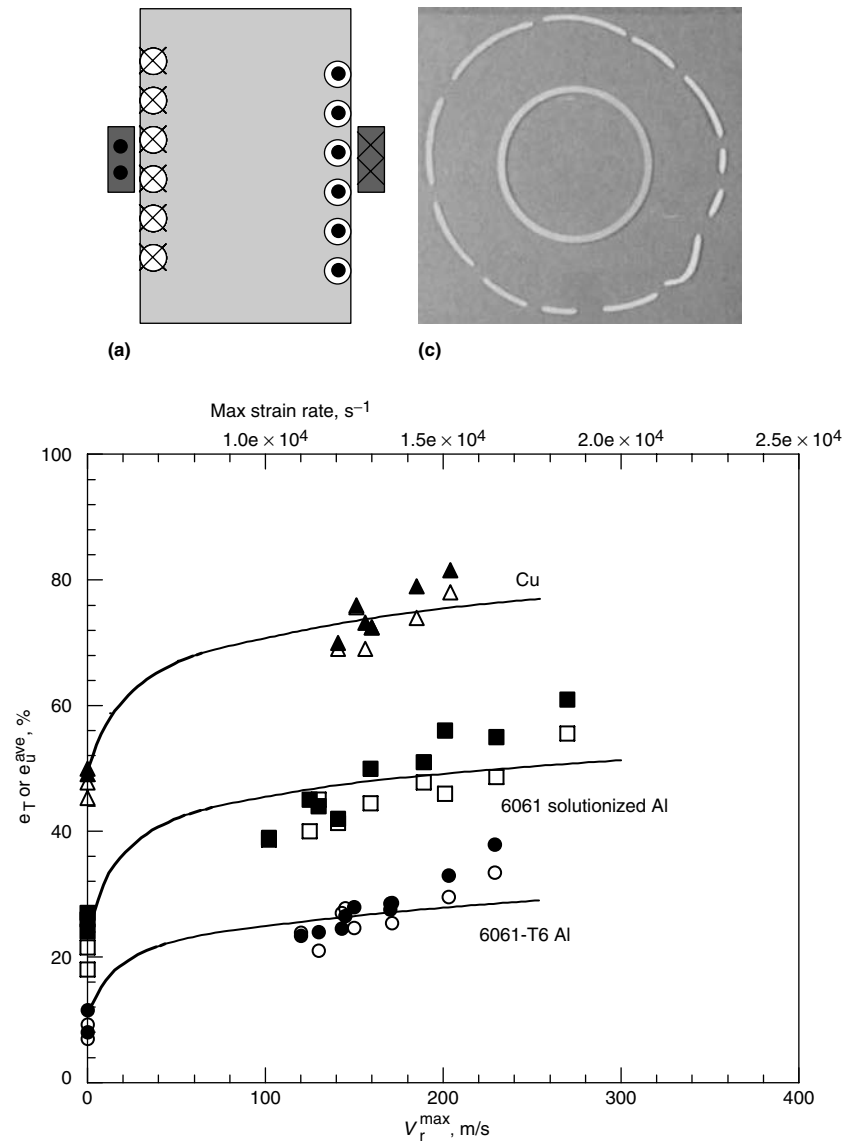

the material will eventually fail. However, at high velocity, the ductility in a slender ring can be doubled versus its quasi-static value, and upon failure, it will break into a number of fragments. Increasing the height of a launched tube or stopping it from high velocity by impact can be used to develop even greater ductility, as detailed elsewhere (Ref 7).

Figure 4 shows a comparison between forming 2024-T4 aluminum into a conical die using quasi-static fluid pressure versus at high velocity using a shock wave developed through electrohydraulic forming. In quasi-static forming, the strains achieved are in good accord with the conventional forming limit diagram. However, when electrohydraulic forming was used, extension strains in excess of 100% were seen (near plane strain and without signs of failure) in

the upper section of the cone. Similar experiments were carried out with copper and iron alloys with similar results. In the case seen in Fig. 4, the strain to failure of the part was increased by a factor greater than 4. Such dramatic increases in formability cannot be explained using the inertial stabilization models used in the discussion of Fig. 2 and 3. The plastic deformation generated when the sheet strikes the die is also important. This will develop a through-thickness compression that deforms the sheet in a manner similar to ironing. This technique is more general than ironing, however, because it is not very restricted with respect to configurations that can be used. As a general summary, in high-velocity forming, one is not constrained by the usual limits prescribed by the forming limit diagram. Instead, if launch and

boundary conditions are properly chosen, ductility far beyond typical quasi-static ductility can be achieved.

**More Uniform Strain Distribution in a Single Operation.** In a practical forming operation, the ability to make a part is not only governed by the formability of a material (which is related to the magnitudes of the strains available without failure), but the ability to uniformly distribute strain is also crucial. The total increase in part surface area is related to the total average amount of stretching over the part. In conventional stamping, friction causes the strain distribution to become quite nonuniform. This problem is particularly important in high-strength materials that have little strain hardening. In punchless forming operations (such as hydroforming, gas pressure forming, or high-velocity forming), the strain distributions can be much more uniform. This will facilitate forming many common component geometries, because strains are more uniformly distributed.

**Reduced Wrinkling.** Inertial forces can also be used to effectively resist wrinkling. Consider a simple example of a ring being compressed radially inward. If this is done at low velocity, the tube will collapse similar to a drinking straw under suction. Under conditions where inertial forces dominate and the tube is launched uniformly, each material point will want to travel radially inward, keeping the circular cross section at each time. Figure 5 demonstrates this schematically and with actual images from ring compression. These results show that inertia strongly suppresses wrinkling in ring compression. Experiments in tube and sheet flanging (Ref 9) show that inertial forces can be similarly effective in inhibiting wrinkling in sheet forming.

**Coining and Detonography.** The very large pressures available from impact or directly from explosives make possible several things that are difficult or impossible with conventional forming. First, by producing a sufficiently high impact velocity, large pressures (Eq 1) can be developed over a large surface. Usually, if fine surface detail is to be captured in a metal surface, it is done with the high-pressure forging process known as coining. Coining pressures usually operate only on small areas (such as coins).

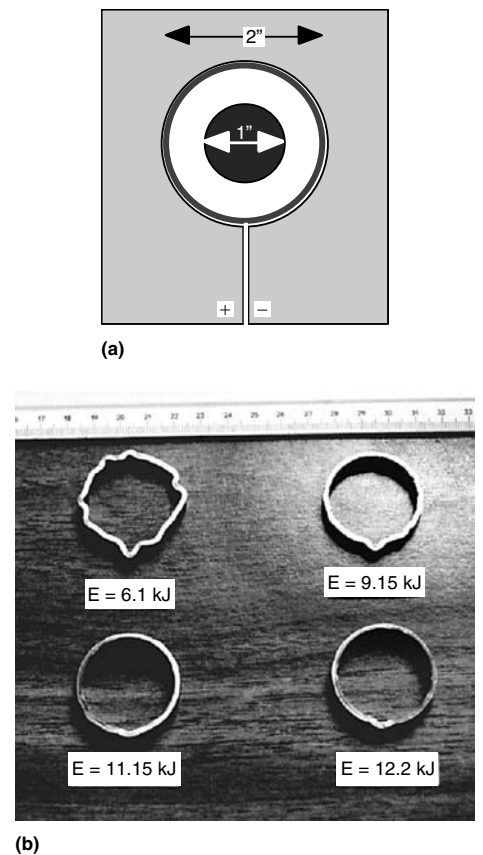

High-velocity forming techniques offer the ability to perform coining-like operations over large areas. An example of this effect appears in the next section.

#### Lightweight Tooling and Equipment.

Although it may seem initially counterintuitive, very light tooling and equipment can be used in high-velocity forming operations. This can be demonstrated with the following simple but quantitative example. Imagine one would like to emboss a 1 m (3.3 ft) square aluminum sheet with exceptional surface detail. The traditional solution to this problem would be to use a coining technique. Coining simply uses a large static pressure to embed the shape in the plate. Typical coining pressures for moderate-strength aluminum are approximately 300 MPa (45 ksi). Thus, a press force of approximately  $300 \times 10^6$  (67.5 million pounds) would be required to do this. This requires a very large press, and this is a key reason coining is only carried out on small items. As discussed earlier (Eq 1 and 2), if the aluminum sheet were accelerated to 50 m/s (165 ft/s) and impacted into a steel die, appropriate pressures can be developed to coin the sheet. Now, imagine specifically, a 1 mm (0.04 in.) thick sheet of aluminum is to be coined, and the steel die is 5 cm (2 in.) thick. By conservation of momentum, if the steel die was completely unrestrained, after impact it would develop a velocity of only 0.34 m/s (1.1 ft/s). A very light framework can easily contain this and dissipate the kinetic energy. In general, because with dynamic and impact events the force will dissipate quickly, much lighter equipment can be used than will be required for static forces.

This potential to reduce equipment size by using dynamic phenomena is true for both simple sheet forming and fluid-pressure forming, such as hydroforming, where again, large pressures acting over large areas require the use of very large presses. Shock wave forming can permit the use of much smaller systems, because the inertia of the forming system itself is primarily responsible for limiting the motion of the machine.

**Natural Interference Fits and Reduced Springback.** The large impact pressure typically generated in high-velocity deformation generally causes sheet metal formed at high

**Fig. 5** Example of electromagnetic high-velocity crimping of thin aluminum tube onto a mandrel. (a) The coil is made from a 1.32 cm (0.52 in.) thick 6061-T6 plate. (b) Behavior of initial 1.651 mm (0.065 in.) thick, 5.08 cm (2.0 in.) outside diameter 6061-T6 rings compressed onto a 3.175 cm (1.25 in.) diameter mandrel at varied indicated launch energies. Source: Ref 9

velocity to closely conform to the shape of the die. One of the primary reasons for this is that on impact with a rigid tool, a plastic wave front will propagate through the sheet thickness; this will cause the residual elastic strains in the sheet to be minimized (these elastic strains cause distortion and springback). Second, on impact, the large pressures will cause the struck surface to displace, and the rebound wave will tend to lock,

producing an interference fit between the sheet component and the die.

There are two important practical implications of this. First, it has been demonstrated that high-velocity forming, which induces impact with a die, can be used for calibration, meaning it can be used to make a sheet workpiece very nearly dimensionally conform with a die surface, even if the contour is so shallow that that shape would normally only introduce elastic strains into the part (and very significant springback) (Ref 10). Second, this can be used to join a tube to a cylinder (Ref 11). This can be accomplished either by expanding into a hollow cylinder or by collapsing onto a cylinder. In either case, natural interference fits between the driven and static tube can be routinely achieved. A simple example of this is shown in Fig. 6. Here, a simple 32 mm (1.25 in.) diameter tube is electromagnetically compressed onto two ordinary hex nuts using two electromagnetic impulses. If the crimping energy is chosen appropriately, a simple crimped joint (i.e., with no metallurgical or chemical bonding) has a strength that is approximately 90% of that of the parent tube. With appropriate fixturing, such joints can have excellent dimensional and alignment precision. They also do not suffer from heat-affected zones or thermal distortion. A more advanced example of this is shown in the examples portion of this article.

**Impact Welding.** The large impact pressures possible in high-velocity forming can also cause extensive plastic deformation near the interface between two mating materials. This can cause solid-state welding to take place between the impacting materials. This type of joining can have several significant advantages relative to traditional fusion welding. Most notably, this is a solid-state process, which is very quick and takes place at relatively low temperatures; dissimilar metals can be joined without the formation of deleterious intermetallic phases. This allows

joining pairs such as aluminum and steel that cannot be joined by fusion techniques, because the iron aluminides that would form are unacceptably brittle.

Several studies have shown that impact welding can be carried out for a range of geometries, including concentric tube cladding, lap welding, and welding tube ends into plates. By far, the most common practical implementation of this is in plate cladding. A detailed discussion of these techniques is beyond the scope of this article, but the basic techniques have been discussed in the literature (Ref 2, 12). Generally, to create a good weld, the surfaces must impact at a relatively high velocity (typically greater than approximately 300 m/s, or 985 ft/s), and they must impact at an appropriate angle. Under these conditions, there is a jetting phenomenon that takes place that cleans nascent oxides off the mating surfaces, and this allows solid-state bonding without extensive chemical reaction. Designing an impact welding process typically involves selecting the standoff between the mating surfaces so that impact takes place, meeting the critical impact velocity and angle. Recently, a technique has been demonstrated for impact welding aluminum, using a projectile and a shaped die, where standoff between the mating sheets is not required (Ref 13). Again, pressure with extensive plastic deformation allows clean metal from the two sheets to meet, because the oxide is disrupted.

**Enhanced Powder Consolidation.** There is fairly extensive literature on the shock wave compaction of both metal and ceramic powders; good summaries are provided in Ref 14 and 15. The fundamentals of the process are quite different than quasi-static compaction. First, the compact is not in static equilibrium; instead, a shock wave moves through the body, producing a distinct boundary between the consolidated and unconsolidated regions. The mass and force distribution that results can often make adding lubricants to the powders less important or unnecessary. Also, the rapid increase in pressure and rapid energy dissipation can cause local heating at particle boundaries. This can soften or often melt a small volume of the powder and can aid consolidation. Lastly, like the examples discussed previously, fairly lightweight compaction systems can produce very high pressures. For all of these reasons, higher density can be developed in dynamic compaction than can easily be achieved with traditional quasi-static compaction. Therefore, sintering steps are sometimes not required to reach target densities. This enables the fabrication of materials such as metal-polymer composites, which are useful as magnetic materials, because they do not effectively transmit eddy currents. The traditional challenge in dynamic powder compaction is avoiding cracks that can be the result of tensile waves, which are the natural consequence of impact operations. Some recent examples show, however, that dynamic powder compaction can be quite effective on relatively complex parts, such as large gears (Ref 16).

## High-Velocity Methods

The old literature on high-velocity forming (Ref 17) documents that a wide range of techniques were used to perform several variants of high-velocity forming or high-energy-rate forming. These included pneumatically driven hammers, exploding gases, and burning of propellants, among others. Of these, there are two that are still used fairly regularly: explosive forming and electromagnetic forming. A third, electrohydraulic forming, has some use but only sporadically and in a few locations. This method essentially combines aspects of explosive and electromagnetic forming. This review focuses on explosive and electromagnetic forming but also briefly discusses electrohydraulic forming and other techniques.

### Explosive Forming

There are a couple of fairly detailed books that have been written on explosive forming and the industrial applications of explosives (Ref 2, 18). These are now fairly old, and while the essential technology of explosive forming has changed little, many analytical tools are now available that were not at the time those books were written. There is also newer literature in impact engineering (Ref 19) and dynamic materials behavior (Ref 20) that is useful but less directly applicable to explosive metal forming. A review of the technology was also recently written (Ref 21).

**Technology Overview.** In order to understand explosive forming, one must first understand some of the essentials of explosive technology. Detailed information on explosives technology can be obtained through the International Society of Explosives Engineers (Ref 22) and their comprehensive background materials, such as *Blasters' Handbook* (Ref 23). There are two general categories of explosives: high and low explosives. Low explosives are substances such as gunpowder that basically burn, generating heat and hot gas. The velocity of the reaction front is much less than the speed of sound. Thus, unless these substances are contained, a shock wave impulse is not obtained. However, they contain enough energy that small masses of gunpowder can do significant amounts of useful work (for example, propelling a bullet down a rifle barrel). High explosives have detonation velocities on the order of 3500 to 8000 m/s (11,500 to 26,000 ft/s) and energies on the order of 1 MJ/kg, as summarized in Table 1. High explosives are available in a wide variety of product forms and compositions, such as granules, powders, shapeable putty, hot-castable compounds, and detonation cord. Detonation cord is especially useful in metal forming, because it allows one to easily prescribe a line source for the explosive event, and it allows the fairly precise handling of the quantities of explosives that are used in metal forming (which are usually much less than those used in typical

**Fig. 6** Example of a 6061-T6 32 mm (1.25 in.) diameter, 1 mm (0.04 in.) wall thickness tube electromagnetically crimped onto four nuts using four electromagnetic discharges and a coil similar to that shown in Fig. 5(a). The nuts are tight after forming and after destructive testing.

mining or military applications). Detonation cord is usually specified in terms of grains (one grain is 1/7000 pound) of explosive per foot of cord, which usually ranges between 10 and 500 grains per foot or 2 to 100 grams per meter.

There are also two types of high explosives: primary and secondary. Primary explosives are relatively easy to detonate and are used to initiate the explosion, usually by means of a blasting-cap configuration. Secondary explosives provide the vast majority of the energy. These are engineered such that they are very difficult to detonate with incidental impact, spark, or flame. Ideally, only a sharp shock wave from something like a blasting cap can detonate them. By properly engineering detonators and secondary high explosives, the explosives industry has developed an excellent safety record, and there are no fundamental reasons explosive metal forming cannot be carried out in a safe and routine way.

In principle, explosive metalworking can be quite inexpensive. A few cents' worth of explosives can perform all but the biggest explosive forming experiments. However, finding a facility where explosive forming work can be carried out is often problematic. The U.S. Department of Transportation governs the transportation of explosive materials. The driver must have a commercial driver's license with a hazardous materials certification. The other main requirement is that explosives be stored in a safe and secure manner. The Bureau of Alcohol, Tobacco, and Firearms (ATF) governs this, and their regulations are summarized in ATF pamphlet 5400.7. Two trade organizations, the Institute of Makers of Explosives (Ref 24) and the International Society of Explosives Engineers (Ref 22), can also be useful sources of information on the use and regulation of explosives.

**Methods of Explosive Forming.** As the voluminous older literature on explosive forming shows, there are a variety of ways that explosives can be used to form or shape metal. There are two types of classifications that can be used to broadly distinguish one kind of process from another. The first is defined by the spatial relationship between the explosive and the workpiece. When very high velocities or pressures are needed, the explosive may be placed directly (or with a thin protective layer) on the workpiece. This is classified as a contact operation. One of the more common contact operations is in the explosive cladding of materials via solid-state impact welding. Standoff operations

are more common in explosive sheet metal forming. Here, the explosive charge is separated from the workpiece by a substantial distance (on the order of the part size). To improve the system efficiency, a transfer medium couples the charge and workpiece. Water is typically used; however, sand and other substances have been used in special cases. The other way to broadly classify forming operations is related to the way the explosion is contained. Most commonly, explosive systems are open. The workpiece, die, and explosive are positioned in what resembles a modified swimming pool. The major modification that is typically made versus a swimming pool is that an array of air bubbles may be generated to blanket the wall of the pool. The purpose of this is to keep the explosive shock from damaging the tank wall. This open approach is quite general, so that almost any explosive/die and workpiece arrangement can be immersed in the tank and formed explosively. One shortcoming of this open technique, however, is that significant energy may be lost in kinetic agitation of the water bath. This can be remedied by using a confined or closed system. Here, the water is largely contained in a strong and rigid enclosure. While this approach has better efficiency and produces less noise, it must be designed carefully in order to achieve adequate die life. Reference 18 has example calculations on sizing dies for confined explosive forming. Lastly, very simple setups can also be used. For example, a plastic garbage bag affixed to a simple support and filled with water lying over the metal to be formed can also act as a bath to contain the explosive charge and comply to the workpiece. This versatility and simplicity in setup is one of the most attractive features of explosive forming.

**Typical explosive forming operations** are summarized here.

**Sheet and Tube Forming.** Explosive forming has been commonly used to form relatively thin sheet metal in standoff operations. If explosives are to be used in contact, something similar to a rubber sheet is often required to protect the sheet. The sheet can either be deformed into a cavity or formed over a male die. Figures 1 and 7 show some examples of sheet forming operations carried out by explosive forming. The main advantage of this technique over more conventional techniques is that one-sided dies are used. This reduces the cost of the forming system as well as the lead time needed to create it. This can

be especially important for large components. Also, extended formability can be observed relative to conventional forming methods. In addition, unlike methods such as superplastic forming, ordinary materials can be used.

Another attractive feature of explosive sheet metal forming is the versatility in die-making procedures. For modest pressures and for relatively small numbers of parts, castable die materials (such as kirkite, fiberglass, urethane, and concrete) can be used. The great advantage of this is that models cut from wood or Styrofoam (Dow Chemical Co.) or created by solid free-form fabrication can be used as the pattern, and a working die can be created very quickly. As with all other die technologies, for higher pressures and longer runs of parts, harder die materials, such as hardened steel, are required.

Explosive forming can be used to develop very high forming pressures (again, often high enough to form tight external radii or emboss the surface). This could possibly be used to augment hydroforming, or, in short run production, this could replace tube hydroforming. Also, because the shock wave strikes the entire surface to be formed at essentially the same time, a single impulse can be used to cut out a series of holes or cutouts in a single operation. Reference 18 provides an analysis and experimental data on such operations. Figure 8 shows an example of a tube that received many perforations as the result of a single explosive impulse.

**Plate Forming.** Explosive forming represents one of the only affordable methods of fabricating large sections from thick plates. Thus, it has often been used to create components such as bulkheads for large pressure vessels and sections of ships and large vehicles. The method has also been used to form several large nuclear reactor components. Contact forming is often used in these situations, because even the availability of an appropriate pool may be problematic. Concrete dies are often used to set the stage.

**Dimensional Tolerance.** Like any manufacturing process, the dimensional tolerance or reproducibility one can obtain from the process is very dependent on the care used in the operation. However, in general, explosive forming operations can have significantly reduced springback as compared to conventional operations (Ref 25). There are a couple of prominent reasons for this. First, the relatively high forming pressures can cause dies to deform somewhat elastically in a manner that opposes springback. Also, the high pressures developed on impact can produce plastic deformation through the thickness of the sheet. This can permit relaxation of the elastic strains that are the root cause of springback distortion. Generally, tolerances on the order of  $\pm 0.025$  mm (0.001 in.) have been obtained in sheet and plate forming of fairly large structures. Small-diameter tubes have also been explosively formed to tolerances of  $\pm 0.025$  mm (0.001 in.).

**Joining and Welding.** Explosives are commonly used to drive joining applications based either on explosive welding or cladding. This is

**Table 1 Common explosives and their typical properties**

Explosive	Form of charge	Deformation velocity		Energy, J/g	Storage life	Pressure	
		m/s	ft/s			GPa	10 <sup>6</sup> psi
2,4,6-trinitrotoluene (TNT)	Cast	7010.4	23,000	780	Moderate	16.536	2.40
Cyclotrimethylene trinitramine (RDX)	Pressure granules	8382	27,500	1265	Very good	23.426	3.40
Pentaerythrite (PETN)	Pressure granules	8290.56	27,200	1300	Excellent	22.048	3.20
Pentolite (50/50)	Cast	7620	25,000	945	Good	19.92	2.89
Smokeless powder	Powder	<1	<3.3	300	Excellent	0.35	0.05

treated well elsewhere (Ref 12). Also, the natural interference fits formed on impact can be useful in joining operations. One example where welding and/or mechanical crimping can be used to form joints is in the explosive expansion of tubes into tubeplates, as takes place in heat exchangers. The British company TEI Ltd. (Ref 26) advertises the use of explosives for bonding of tubes to tubeplates in heat exchangers, expanding tubes into structural

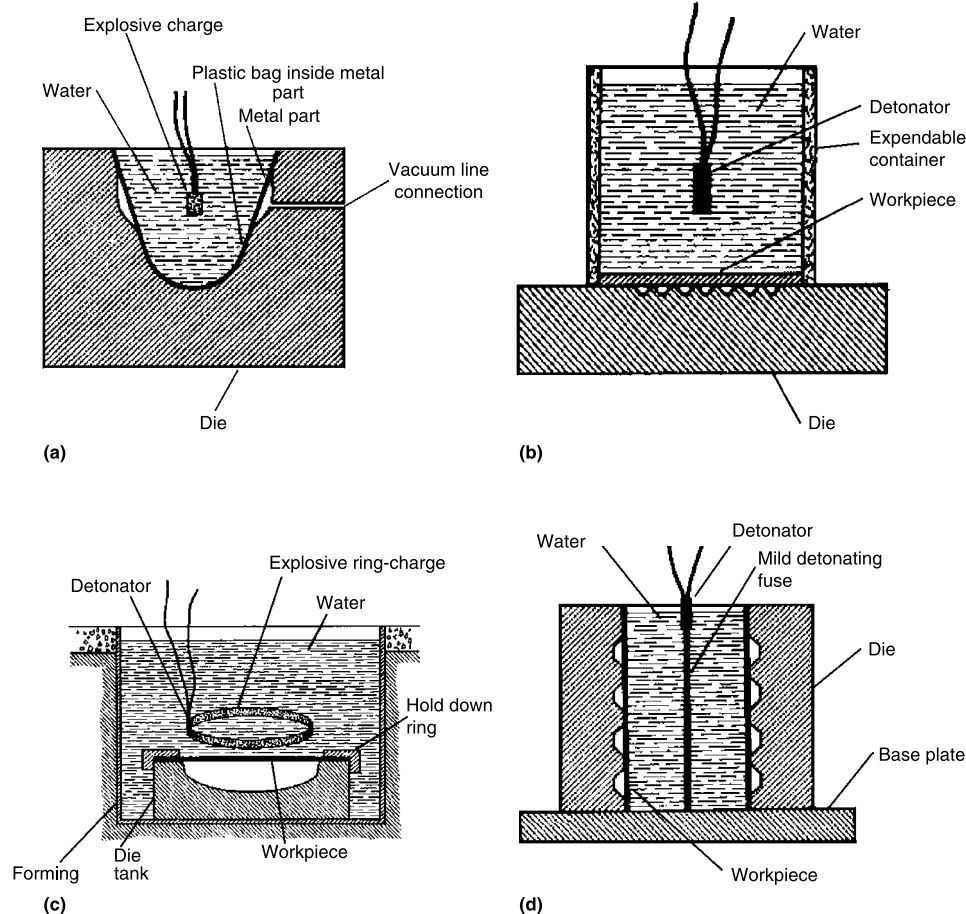

supports, as well as expanding sleeves into corroded or worn tubes for life extension. They also use the same basic explosive technology for the removal of adherent scales in power plant applications.

### Electromagnetic Forming

**Basic Physics.** Electromagnetic forming is a noncontact technique where large forces can be

imparted to any electrically conductive workpiece by a pure electromagnetic interaction. The physics of this interaction are covered fairly well in several sources (Ref 14, 17, 27, 28); only a short description is included here. A schematic diagram is provided in Fig. 9. The process is driven by the primary circuit, labeled "1." A significant amount of energy (usually between 5 and 200 kJ) is stored in a large capacitor or bank of capacitors by charging to a high voltage (usually between 3000 and 30,000 V). The charge is switched over low-inductance conductive buswork through a coil or actuator. Large currents run through the coil. The currents take the form of a damped sine wave and can be understood as a ringing inductance-resistance-capacitance (LRC) circuit. The peak current is typically between approximately  $10^4$  to  $10^6$  amperes, and the time to peak current is on the order of tens of microseconds. This creates an extremely strong transient magnetic field in the vicinity of the coil. The magnetic field induces eddy currents in any conductive materials nearby in much the way the primary circuit of a transformer induces voltage and current in the secondary. Hence, any metallic workpiece nearby will have currents induced, and these will generally be opposite in direction to the primary current. The opposed fields in the coil and workpiece set up an electromagnetic repulsion between the coil and workpiece. That electromagnetic force can produce stresses in the workpiece that are several times larger than the material flow stress. Ultimately, this can cause the workpiece to deform plastically and to be accelerated at velocities exceeding 100 m/s (330 ft/s). The key governing equations for this process are also summarized in Fig. 9.

Developing a relatively high system ringing frequency is often quite important. If the electrical oscillation frequency is too low, intense eddy currents are not induced in the workpiece, and the force developed is low. The ringing frequency is directly related to the circuit LRC characteristics, and low capacitance and low inductance favor a high ringing frequency. Materials of lower conductivity demand higher ringing frequency for effective forming. For these reasons, metals with high conductivity, such as aluminum and copper, are very well

**Fig. 7** Schematic examples of typical explosive forming operations. (a) Sizing with a water-filled die cavity. (b) Method for forming a flat panel. (c) Use of detonation cord to prescribe the pressure distribution in an open forming system. (d) Use of detonation cord to form a cylinder. Open- or closed-die systems can be used. Source: Ref 2

**Fig. 8** Example of a 4130 cylinder given multiple perforations in a single explosive operation. Source: Ref 17

where  $L_1 = L_p + L_c$ ,  $R_1 = R_b + R_c$

**Fig. 9** Schematic of the general electromagnetic forming process with key equations

$$\begin{aligned} \frac{d}{dt}(L_1 I_1 + M I_2) + R_1 I_1 + \frac{Q_1}{C_1} &= 0 \\ \frac{d}{dt}(L_2 I_2 + M I_1) + R_2 I_2 &= 0 \\ P_m &= \frac{1}{A} \frac{dM}{dh} I_1 I_2 \end{aligned}$$

suiting to electromagnetic forming. Carbon steel can be formed, but one should pay attention to the system ringing frequency. Metals with relatively low electrical conductivity, such as titanium and austenitic stainless steels, are almost impossible to directly form by electromagnetic forming (but they can be formed with the aid of a more conductive driver plate).

Historically, the workpiece has usually been a tubular metal piece that is either expanded or compressed using a helical electromagnetic coil. These applications are particularly efficient and easy to model. However, the process is actually quite versatile, and the workpiece may be cylindrical, a flat sheet, or an arbitrarily curved surface. In making an actuator that would act against an arbitrarily curved surface, one would like to place a forming coil in close proximity to the sheet. A continuous sheet will generally find a way to support eddy currents to develop mutual repulsion. A complete calculation of the spatial and temporal distribution of force is difficult, particularly when the sheet is moving and deforming while the electromagnetic force is being applied. However, it is useful to develop a quantitative estimate of the electromagnetic pressures present. An upper bound on force on the sheet can be roughly calculated with the following assumptions and principles:

- The electromagnetic force will always act normal to the plane of the sheet. It can be seen as being driven by the magnetic flux between the actuator and workpiece wanting to expand to fill space.
- If both elements are highly conductive and close enough to each other to be electromagnetically well coupled, and the actuator width is large relative to its gap, it is appropriate to make the assumption that the current in the workpiece is equal and opposite to the current in the actuator.

Under this upper bound assumption, the magnetic pressure,  $P_m$ , in the region between the actuator and conductor can be approximated as:

$$P_m = \frac{\mu_0 H^2}{2} \quad (\text{Eq 3})$$

where  $H$  is the electromagnetic field intensity, expressed in amperes per width. Thus, decreasing the width of a conductor or increasing the number of turns can both powerfully increase the magnetic pressure. A version of this equation that is often simpler to use states that magnetic pressure in megapascal units can be related to the current density in the conductor (in units of KA/cm or KA·turns/cm) as:

$$P_m = 0.0063 H^2 \quad (\text{Eq 4})$$

Actually, if the current densities in the primary and secondary conductor are known by estimate or measurement,  $H^2$  can be replaced with the actual product of these current densities. The equation will be accurate so long as the gap between the current-carrying elements is small with respect to their in-plane dimensions. The

peak current generated by a capacitor bank discharge,  $I_{\max}$ , can be estimated from standard LRC equations for the primary circuit. As long as the circuit resistance is low, this can be estimated as:

$$I_{\max} = V_0 \sqrt{\frac{C}{L}} \quad (\text{Eq 5})$$

where  $V_0$  is the voltage the capacitor bank is initially charged to, and  $L$  is the total system inductance. At a fixed primary circuit current, the magnetic pressure (electromagnetic field intensity) is increased by increasing the number of windings in the forming coil or solenoid, but this will increase the inductance of the system. This in turn reduces the peak current. The result is that for any situation, there are an optimal number of coil windings. As a general rule for efficient forming, most of the total system inductance should reside in the forming coil. There is an engineering trade-off, however; as the number of turns increases, the inductance of the system rises, reducing ringing frequency. This reduces the peak current and will allow more flux to leak through the workpiece.

The correspondence between electromagnetic field intensity and magnetic pressure can be exploited in the design of electromagnetic forming coils. For example, Fig. 10 shows a simple coil created by machining a thick plate. In regions where the current paths are closely packed, there will be a much higher pressure than in regions where the coil has thick, sparse conductors. This ultimately determines the launch velocity distribution for the sheet and the free-form shape the sheet metal shape would take.

**Equipment.** An electromagnetic forming system has two essential electrical components—a capacitor bank and a forming coil—that do work on a workpiece to be formed. Also, some tool or die system that produces the final part shape may also be important. There are two opposing philosophies that one may follow in developing an electromagnetic forming system. One could develop a general-purpose setup that is useful, but not optimal, for a range of metal forming activities. Or, a system may be designed that is optimal for a particular operation. In this latter case, one can be much more efficient (developing equivalent metal forming with less stored electrical energy). These approaches become clear when system details are discussed.

**Capacitor Banks.** The heart of an electromagnetic (or electrohydraulic) forming system is a capacitor bank. The essential components are a number of capacitors that store energy,  $E$  (typically in the range of 5 to 200 kJ), by storing electrical charge at voltages,  $V$ , between 3 and 30 kV. The associated bank capacitance,  $C$ , can be determined from:

$$E = \frac{CV^2}{2} \quad (\text{Eq 6})$$

The energy is provided to the capacitors by a charging system. A transformer steps the voltage up from line voltage to that required by the

capacitor bank. The capacity of the transformer will largely control the time required to charge the bank between discharge events. In repeated use, active cooling of the elements that dissipate energy will limit the ultimate cycle period for such a bank.

The capacitors are tied to the current output with buswork. Two considerations are key in the design of the buswork: it must have low inductance (in general, the majority of the system inductance should be at the forming coil), and long-lasting spark-free electrical contacts are required.

In use, the capacitors are relatively slowly charged to the forming voltage, and once this is reached, a fast-action switch is used to provide the current pulse to the coil. Several types of switches have been used, including rat-trap-type switches and fairly simple spark gaps. Commercial capacitor banks typically have either mercury-filled ignitron-type switches or solid-state silicon controlled rectifier switches. The former perform well but can be temperamental and have a somewhat limited life, while the latter can be inefficient if not designed well, and it can be expensive to equip the bank with the number of switches required to handle the large currents seen in electromagnetic forming.

In a simple LRC-type circuit, the current will ring with a damped sinusoidal current-time profile. However, a high-capacity diode is often put in parallel with the circuit. This allows only the first half-cycle of the sine wave to be output. Because most of the useful work is done in this first half-cycle, this has little downside and has the benefit of adding life to the capacitors as well as limiting damage and sparking at contacts. The disadvantage of a clamped (diode-including) capacitor bank circuit is that if too large a current runs through the diodes, they will burn out. Such events may be rare in a steady-state manufacturing environment, but shorts or low-inductance coils may be common in research and development applications.

**Fig. 10** Example of a coil designed for forming flat sheet where the electromagnetic field intensity is intentionally varied from place to place. In this case, the coil is simply machined from a high-strength aluminum plate. Much higher magnetic pressure is developed in the bottom half of the coil than in the top.

**Coils.** There are several different philosophies on how electromagnetic forming actuators can be fabricated, and different approaches have different optimal capacitor bank system characteristics associated with them.

**Single Turn and Machined Actuators.** The simplest way to make an electromagnetic compression coil is simply to cut a slot and hole in a conductive plate, as shown in Fig. 5(a). High material conductivity will improve system efficiency, and high material yield strength provides a strong, robust, long-life coil. High-strength aluminum alloys, copper-beryllium alloys, brasses, and oxide-dispersion-strengthened materials such as Glidcop (OMG Americas Corp.) are all good candidate coil materials. Polyamide films such as Kapton (E.I. du Pont de Nemours & Co.) can provide insulation in a convenient way.

This basic approach of machining coils from relatively thick, flat plate can also be used to form effective actuators for the electromagnetic forming of flat or curved sheet. Figure 10 shows an example of such a coil. As discussed previously, the shape of the coil determines the pressure distribution and launch velocity distribution for the sheet.

**Multiturn Coils.** Often, electromagnetic forming actuators are fabricated by the simple coiling of conductive wire (often common copper magnet wire) over a strong nonconductive mandrel such as grade G-10 laminated phenolic composite (or a single-use coil can be created by using only the wire itself). Reinforced epoxy or urethane is often used as a structural and insulating overlayer. Compression, expansion, or flat coils can all be made following this same general approach. There are two important limitations of this type of coil. First, the forces on the workpiece and coil are equal and opposite (in addition to other magnetic interactions within the coil). Therefore, the coil construction materials determine the pressure the coil can withstand. For this reason, coils of this construction are usually limited to pressures on the order of 48 MPa (7000 psi), if they are to be used for many

operations. Second, it is usually difficult to use a very fine winding pitch to increase local field intensity. This also limits the local pressures that can be generated from this kind of coil. Both of these issues can be partly treated in short-run production by using inexpensive coils that are essentially disposable.

**Field Shaper.** In general, the highest electromagnetic pressures can be generated when the working surface of the coil is made from a monolithic block of a high-strength (and high-conductivity) metal. Hence, large pressures can often be created with single-turn coils, but because single-turn coils typically have quite low inductance, they are often quite inefficient. Field-shaper-based coils can be used to develop high electromagnetic pressure while being able to increase and tailor the inductance of the coil. The principle of a field shaper coil is illustrated in Fig. 11(a) (b) and (c). A typical multiturn coil is used to create a magnetic field. This is coupled to a secondary inductor or field shaper. As schematically described in Fig. 11, if properly designed, essentially the entire current flux (amp·turns) that is created in the primary current can be transferred to the bore of the shaper. The advantage of a coil of this type is that it can concentrate large magnetic pressures in a desired area. This is done at the cost of being less efficient than a well-designed single-stage coil. Figure 11(c) shows a production coil with field shaper. Notice that the primary conductor, which is connected to the high-voltage side of the capacitor bank, is embedded in a secondary coil core. To enhance safety in a production environment, the core is electrically isolated from the primary winding. It is only electromagnetically coupled to it. It is also liquid cooled. The current is then transferred from the primary to the coil core secondary and then to the field shaper. This type of coil will accept field shapers with varied forming diameter, which makes it extremely versatile. Thus, a single coil with a number of varied inserts can be applied to a wide range of compressive forming operations. This basic approach has been creatively applied to making

coils of many types for many operations (Ref 29). Another common application of the field-shaper concept is shown in Fig. 12, which shows a common wafer coil. Coils of this type can generate very high electromagnetic pressures (up to approximately 350 MPa, or 50 ksi) repeatedly without failure.

**Typical Applications.** While electromagnetic force can be used in very general and creative ways to form conductive sheet metal, to date it has been almost exclusively used to form crimped assemblies that resemble those shown in Fig. 6. Such assemblies can be designed to optimize axial or torsional strength, and in either case, the joint strength can often exceed the strength of the parent tube. Despite this, most of the assemblies that have been produced do not require high mechanical performance. Instead, the high reproducibility and dimensional tolerance afforded by the process are more typically the reasons for choosing electromagnetic crimping. The technology has also found application in the aircraft maintenance industry. Magnetic hammers are used (Ref 30), and a somewhat more complex application of this has been developed to create electromagnetic dent-pullers (Ref 31).

### Electrohydraulic Forming and Other Methods

In many regards, electrohydraulic forming is a hybrid between explosive forming and electromagnetic forming. Here, an intense liquid-based shock wave is produced by an intense electrical current vaporizing a small volume of liquid in a spark gap between two electrodes. The current pulse is produced using essentially the same equipment (capacitor banks) that produces the currents in electromagnetic forming. However, the liquid-based shock wave that results is very similar to what would be produced by an explosive point or line charge. The energy efficiency of this technique is similar to that for electromagnetic forming.

**Fig. 11** Field shaper coils. (a) Behavior of a field-shaper-based coil looking at the coil cross section. The many turns of the primary coil induce a current in the shaper. (b) The situation looking down the axis of the shaper. A slot in the coil forces the current to the bore of the coil, concentrating current there. (c) Practical construction of a field-shaper-based coil

Electrohydraulic forming is not widely practiced; however, a few companies do use it for short-run production (Ref 32). It is better controlled than explosive forming and therefore more amenable for operation in usual factory conditions. However, it is difficult to access the same quantities of forming energy that explosive forming can. Reference 17 contains a good review of this technique. The use of electrohydraulic forming is described in Example 4 in this article.

In addition to electrohydraulic and explosive forming, other methods for developing a pressure pulse in water have been considered. For example, Ref 33 examines methods of water-hammer forming. Also, for forming small features, water-pulse methods and electromagnetic methods may be quite inefficient. In these cases, it is possible to use a deformable projectile traveling at a high velocity to accomplish metal forming. This can quite easily develop high strain rates and pressures over a small area. This technique has been demonstrated for solid-state welding (Ref 13) and is an excellent candidate technique so long as the area to be formed is smaller than the projectile.

**Fig. 12** Heavy-duty wafer-type compression forming coil, which is also based on complied primary and secondary coils. ### Hybrid Methods

There are a number of ways that the impulse-based metal forming methods discussed in this article can be used on their own to accomplish many metalworking tasks. These methods are not commonly practiced, but they are effective and robust. Traditional displacement-controlled forming is usually chosen because these methods are well developed, understood, and (except for springback) the part shape is definitely determined by the forced conformation with a hard tool. Impulse-based methods can offer improved strain distribution and formability, springback reduction, and the ability to add crisper part detail. In many instances, it may be best to use impulse-based techniques only in regions where these special advantages are required. The following brief discussion is broken into two subsections. The first deals with augmenting the matched-die systems that are at the heart of mass production stamping. The second section addresses using one-sided dies as are used in hydroforming, which dominates aircraft production and is used in other low-volume processes such as prototyping. In both cases, the general goal is to get the best from established methods while treating difficult part features by using impulse-based metal forming methods where needed.

**Hard Tool.** Electromagnetic forming coils can be rather simply embedded into traditional stamping tools (Ref 34). These actuators essentially add new degrees of freedom to the forming process, allowing operations to be completed in a single press tool that would typically require multistage forming operations. Figure 13 shows two different approaches for integrating electromagnetic forming tools with stamping systems. Figure 13(a) shows a system where traditional tooling is used to make the bulk of the shape, but discrete features and corner radii, for example, require greater formability than the material can offer. These features can be created using a single electromagnetic pulse that can be applied at the end of the forming cycle. This will create

the relatively small but difficult feature. This basic approach has been demonstrated in the context of forming an automotive door inner from aluminum (Ref 35) and is briefly summarized in the examples part of this article. Typically, aluminum does not have sufficient formability to form a door inner, and an electromagnetic actuator was used to put a sharp corner in a panel that had a large radius of curvature put in by traditional forming.

The approach of using a single electromagnetic discharge to form a feature (Fig. 13a) has two drawbacks. First, quite high magnetic flux densities are required to give sufficient electromagnetic force to create the feature in a single discharge. This makes the development of long-life actuators a challenging issue. Second, in making features by a single high-velocity impulse, die bounce-off at areas of high strike velocity can make it difficult to maintain dimensional tolerance. These drawbacks can be avoided by using a number of electromagnetic pulses in a hybrid tool of the type shown in Fig. 13(b). The key idea here is that the capacitor bank is optimized for quickly producing a large number of small electromagnetic pulses, and it is coupled to coils in regions of the tool where increased strains are required in order to make a part. The setup is shown schematically in Fig. 13(b). Typically, in forming such a part, the sheet will neck and tear just outside the punch perimeter. The sheet can be stretched in regions 2 and 3 to add strains that can provide increased line length to provide further punch displacement. Also, actuators 1b and 1a can be sequentially discharged in order to facilitate sheet draw-in into the die. This can be efficiently carried out by using many (5 to 50) small discharges to strain the sheet just a few percent with each discharge and by moving the tool with each cycle to re-establish contact between the sheet and actuator. This avoids the challenging issues associated with handling the large and potentially destructive energies associated with forming with a single discharge designed to develop large strains. The hard die set controls part shape, and

**Fig. 13** Two concepts of how electromagnetic forming coils can be used profitably in press systems. (a) Single significant discharges can be used to sharpen or add features that would cause failure of the part if they were produced in the initial stamping operation. Increases in formability and improved strain distributions aid the situation. (b) Schematic demonstration of a press where a large number of small discharges can be used to aid draw-in (region 1) and to produce strain in desirable areas (region 2). After strain or displacement, the punch is moved to re-establish close proximity between the sheet and coil.

the relatively small pulses required to produce only a few percent strain with each impulse are not damaging on the electromagnetic coils.

**Single-Sided Tool.** In applications where on the order of 100 or fewer parts of a particular shape are required each year, the design and manufacture of the matching tools that are used in stamping operations is cost-prohibitive. As a result, in the aircraft and aerospace industries, single-sided (or so-called soft) tools are commonly used. A large fraction of doubly-curved parts used in aircraft production are created by rubber pad hydroforming. In this process, a large rubber mat is subjected to fluid pressure on one side, and this is used to drive sheet metal into a single-sided die. Often, these dies can be made from materials that are inexpensive to shape, such as masonite and kirsite. There are two persistent problems associated with hydroforming. First, although the strain distribution can be improved relative to double-sided hard tooling (because frictional forces are generally reduced), material forming limits often limit the ability to make a given part in a single operation. The usual approach for treating the problem associated with the material forming limit is to only partially form the part (by using a pressure that is only a fraction of that needed to completely form the part), remove the part from the die, wash off all lubricants, anneal the part to soften it, re-lubricate it, and place it in the die where a larger pressure is now applied. Many such cycles may be used to fabricate the part. The other problem in forming with soft tooling is springback. Usually, the tool is cut to the required contour, and springback is treated by manual deformation back to shape with soft hammers.

Two hybrid concepts that can aid the situation with soft tools are shown in Fig. 14. Figure 14(a)

**Fig. 14** Hybrid methods for use with soft tools. (a) Use of an electrohydraulic impulse in conjunction with sheet hydroforming. Hydroform forms the basic shape, while the shock wave imparts detail. (b) Use of electromagnetic coils to influence the strain distribution in electromagnetic augmented hydroforming

shows the use of an electrohydraulically or explosively generated shock wave that can be used to form features that may need improved definition (such as sharper corners) or improved formability (such as recessed regions in otherwise flat panels). There are significant advantages of such an approach. First, all of the issues discussed with respect to formability, reduced springback, improved part definition, and blanking of features can be accessed with such a method. Second, the approach may ultimately be less expensive with respect to both equipment cost and cost per article. This is because the peak pressure in a hydroforming process determines the sharpness of features that can be formed. High static pressures require large equipment and longer cycle times. If the high pressure is obtained by an explosive or electrohydraulic impulse, the cycle time could be much shorter and delivered from smaller and less expensive pumps and enclosures.

Figure 14(b) demonstrates another concept that could be useful with soft tooling. It is closely related to the approach discussed in Fig. 13(b). Electromagnetic forming coils can be embedded into a hydroforming die, as shown in Fig. 14(b). The electromagnetic repulsive pressure between the coil and sheet can be several times that of the fluid pressure. This would cause the sheet in the proximity of the coil to move away and stretch in this region. Once the magnetic pressure naturally dissipates, the fluid pressure will naturally move the sheet back to the die, but it will have stretched in the area of the electromagnetic coil. This will cause controlled stretching and motion of the sheet. The important element in designing systems of this type is to place the coils either in regions that see insufficient stretch (such as regions 1 to 3 in Fig. 14b) or in areas that can encourage the part to draw in at a fixed fluid pressure. If uniform strain can be encouraged in this way, the multiple cycles of forming, cleaning, annealing, and reforming could be reduced or avoided.

## Forming Examples

**Example 1: Electromagnetic Forming and Piercing.** Figure 15 shows an example of how versatile the process is and how, with some

ingenuity, very simple forming operations can be developed to form complex parts. The tubular part shown in Fig. 15 was produced in one electromagnetic forming operation using an expansion coil to form, flange, and pierce a length of tubing against a single-piece die. The workpiece was a 100 mm (4 in.) length of 6061-O tubing with an 83 mm (3.25 in.) outside diameter and an 0.89 mm (0.035 in.) wall thickness.

The die was turned from 4340 steel tubing with a 12.7 mm (0.5 in.) wall thickness. Two drilled holes are used for the piercing operation. The formed part was removed from the die by means of a simple ejector. The parts used a 6 kJ impulse for forming, and production rates of 240 pieces per hour could be achieved using only manual loading and unloading.

**Example 2: Aluminum Automotive Door Inner Panel.** In collaboration with the automakers, The Ohio State University carried out a demonstration of electromagnetically assisted stamping that conforms generally to the hard tool hybrid forming approach discussed earlier and shown in Fig. 13(a). The experimental approach and results (detailed in Ref 35) involved a trial of electromagnetically assisted stamping to allow forming of aluminum door inners. Aluminum door inners can provide weight savings (about 6 kg per door), but the formability of aluminum is poor relative to steel. Without substantial changes in the product geometry, the door inner is not even close to fabricable using traditional press operations.

The hybrid electromagnetic-assisted stamping process was used to treat the GM J-Car hinge face. The concept was to soften the corner (Fig. 16) on the hinge face of the door in such a manner that the door was formable and then use an electromagnetic actuator to reform the door panel into the required shape. This was carried out in two discrete operations, but the concept can be carried out in one press stand.

Despite the successes, this experiment points to reasons that the approach of using many small impulses to form the material may be superior. In this example, a forming energy of approximately 36 kJ was required to change the shape of the preform to the final shape. This produced currents near 500 kA in the coil. It is presently difficult to design, build, and predict remaining

**Fig. 15** Forming and piercing of a tubular part in one operation

lifetime for coils that are so heavily mechanically and electrically stressed. Another problem with the approach is that the final shape of the part is not directly controlled. In the experiment, the final shape was very close to that required. However, a restrike operation may be required to meet required tolerance.

**Example 3: Hybrid Incremental Forming.** The concept of using a series of small electromagnetic discharges to alter the strain distribution in sheet metal parts has been tested (Ref 34). Figure 17 shows a series of images related to this. Figure 17(a) shows a coil path that was inserted into a die. An electromagnetic pressure acts along this line when the actuator is energized by a capacitor bank discharge. During the stamping process, the clamp load is fixed, and the punch is advanced a prescribed amount between discharges. This is repeated with each discharge until failure. A result of hybrid incremental forming is shown in Fig. 17(b). It shows that the draw depth of the parts can be dramatically increased without any reliance on lubricants. The draw depth increased by 44% (from 4.4 to 6.35 cm, or 1.7 to 2.5 in.). This experiment shows that the approach of placing forming energy where required can significantly increase the ability to make aggressive sheet metal parts. The effect of the embedded electromagnetic coil is to produce tensile strain across the top surface of the part, and the tooling system defines the part shape in the usual way. Figure 17(c) shows the punch force versus stroke profile for the standard process and the electromagnetically assisted bump forming process. In the electromagnetically assisted process, with each cycle the strain across the top reduces the punch force. This reduction in punch force ultimately is responsible for the delay in tearing. Figure 17 represents one of the first experiments of this kind to be carried out. It simply shows that formability can be significantly enhanced and electromagnetic actuators can be embedded in forming dies. Better results will certainly follow as this type of process is further developed and improved.

**Example 4: Auto Body Prototype Forming.** Explosive and electrohydraulic forming represents cost-effective alternatives to hydroforming in the prototyping of auto body panels. The pressure pulse in water holds several advantages

**Fig. 16** Hybrid electromagnetic-assisted stamping process used to form hinge faces on aluminum inner door

to hydroforming: formability can be increased, peak pressures attained can be much higher, and springback can be reduced. Both approaches have been used for the low-volume production of aircraft parts as well as for prototype automotive parts, primarily in the former Soviet Union.

## Joining Examples

**Example 5: Solid-State Impact Welding.** If two metals strike at an appropriate velocity (typically above 300 m/s, or 985 ft/s) and angle (typically approximately  $10^\circ$ ), they will often form a solid-state metallurgical bond. Dissimilar metals can often be bonded without the deleterious effects of intermetallic formation that limit the use of fusion welding for dissimilar metals. Explosively clad plates can be purchased that are based on this solid-state welding approach. Basically, explosives are placed in contact with the cladding metal that is given an appropriate standoff from the base metal plate. When the explosive is detonated, the contact angle between the cladding and base metal is determined by a combination of the explosive detonation velocity, the clad metal velocity, and the original standoff distance. Reference 12 summarizes both the theory and practice in this area.

In recent years, there has been considerable interest in using electromagnetic pulses to provide the impulse required for solid-state welding. Such techniques have the advantage of being better adapted to joining small articles (such as tubing, driveshafts, or automotive frames). They are more controllable and reproducible. Also, they do not require the use of high explosives. While electromagnetic pulse welding techniques

have been demonstrated at least as early as 1978 (Ref 37), they still have not been widely commercialized. This is in part because the process is somewhat difficult due to the high impact velocities that are required for robust joining. This makes it difficult to develop long-life electromagnetic coils that can repeatedly produce the required high pressures.

**Example 6: Lightweight Torque-Carrying Shafts.** For many demanding structural applications, crimping can be used instead of the formation of metallurgical welds to carry force or torque. Structural crimping does not require the large impact velocities that are necessary in impact welding. One of the most impressive applications of electromagnetic crimping is in high-lift torque tubes, which Boeing uses in its 777, 737, and 747 aircraft. Here, 0.325 cm (0.128 in.) wall thickness aluminum alloy tubes are crimped onto steel yoke fittings. Peak electromagnetic pressures of approximately 205 MPa (30,000 psi) are created from a 60 kJ energy storage bank. Figure 18 shows a typical manufacturing system for torque tube assembly. Figure 19 shows the detail on a torque tube joint, including a tube after destructive torsion testing. The tube does not fail in the joint but in the parent material. These tubes have been shown to have a fatigue life equivalent to several times the life of the airframe structure. This electromagnetic crimp replaces a design that was troublesome with respect to fatigue.

## Technology Status

High-velocity forming methods have a long and significant history. However, these

techniques have never quite achieved a clear place among mainstream manufacturing methods. This may be attributed to the fact that there is little intersection between the communities that understand capacitor bank discharge or explosive engineering with the metal forming community. As a result, neither toolmakers nor engineers have become comfortable with or trained in these methods, and hence, they are not used.

Precisely because these methods are very different than conventional metalworking by stamping, they may be very well suited for treating many issues that are difficult with conventional technology (formability, strain distribution, controlling springback, etc.). Although these techniques have fundamentally been known for a long while, there remain significant opportunities in their development and application.

# Drop Hammer Forming

DROP HAMMER FORMING is a process for producing shapes by the progressive deformation of sheet metal in matched dies under the repetitive blows of a gravity-drop hammer or a power-drop hammer. The configurations most commonly formed by the process include shallow, smoothly contoured double-curvature parts; shallow-beaded parts; and parts with irregular and comparatively deep recesses. Small quantities of cup-shaped and box-shaped parts, curved sections, and contoured flanged parts are also formed.

**Advantages and Limitations.** The main advantages of drop hammer forming are:

- Low cost for limited production
- Relatively low tooling costs
- Dies that can be cast from low-melting alloys and that are relatively simple to make
- Short delivery time of product because of simplicity of toolmaking
- The possibility of combining coining with forming

These advantages must be weighed against the following limitations:

- Probability of forming wrinkles
- Need for skilled, specially trained operators
- Restriction to relatively shallow parts with generous radii
- Restriction to relatively thin sheet (approximately 0.61 to 1.63 mm, or 0.024 to 0.064 in.; thicker sheet can be formed only if the parts are shallow and have generous radii)

Drop hammer forming is not a precision forming method; tolerances of less than 0.8 to 1.6 mm ( $1/32$  to  $1/16$  in.) are not practical. Nevertheless, the process is often used for sheet metal parts, such as aircraft components, that undergo frequent design changes or for which there is a short run expectancy.

## Process Description (Ref 1)

The drop hammer forming process methods can be classified into three categories: bare punch, blow down, and blow up. Bare punch is the simplest procedure, using a single hammer blow and no forming aids. Blow down and blow up procedures require the use of forming aids and

multiple punch blows (Fig. 1). The most commonly used forming aids are made of rubber, because this has the ability to flow like liquid when squeezed or impacted. The rubber sheets are placed on (blow down) or under (blow up) the part to form a pyramid. During the forming process, the pyramid causes the impact force to flow in the direction of the least rubber buildup, thus preventing wrinkles and folding. After each punch blow, one or two sheets of rubber will be removed before the next punch blow is applied. The distance of the punch blow may vary depending on the part and die configuration.

Key factors in determining a process plan include:

- Type of part material
- Type of tool (male or female)
- Maximum draw depth of the tool
- Number of corners of the part

**Part Material Type.** Three types of part material are used frequently, namely, aluminum, steel, and titanium. The material of the part can determine the selection of different types of rubber as forming aids. For example, because titanium is very hard, usually the part is heat treated (above 600 °C, or 1100 °F, for 10 min) before the forming process is applied. As a result, harder and heat-resistant rubbers are needed as forming aids.

**Type of Tool.** Generally, there are two types of tool according to their geometric configuration, namely, male and female. The geometric configuration determines where forming aids (rubber sheets) can be placed, that is, on or under the part. The determination of tool type is not always straightforward, because it depends not only on the tool geometry but also on the part geometry. For example, a male tool may be considered when the part is formed using the rib located in the middle of the tool. A female tool is considered when the part will be drawn into the cavity during forming.

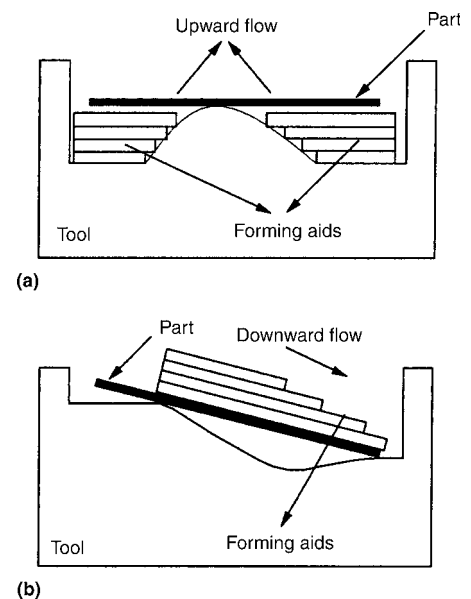

**Maximum Draw Depth.** The maximum draw depth, to some extent, determines the number of hits the operator should apply during the drop hammer forming process. Softer materials, such as aluminum and mild steel, can be drawn in one stage to approximately 50 mm (2 in.). However, hard material, such as titanium, can only be drawn in one stage to approximately 13 mm (0.5 in.).

**Number of Corners.** The severity of permissible deformation in drop hammer forming is limited both by geometrical considerations and by the properties of the work metal. The number of corners is a major geometrical consideration that influences the determination of process conditions.

## Hammers for Forming

Gravity-drop hammers and power-drop hammers are comparable to a single-action press. However, they can be used to perform the work of a press equipped with double-action dies through the use of rubber pads, beads in the die surfaces, draw rings, and other auxiliary equipment.

Because they can be controlled more accurately and because their blows can be varied in intensity and speed, power-drop hammers, particularly the air-actuated types, have virtually replaced gravity-drop hammers. A typical air-drop hammer, equipped for drop hammer forming, is shown in Fig. 2.

**Fig. 1** Process methods with forming aids. (a) Blow up. (b) Blow down. Source: Ref 1

Power-drop hammers are rated from 4.5 to 155 kN (1,000 to 35,000 lbf), representing energies from 15 to 575 kJ (11,000 to 425,000 ft·lbf). Air-drop hammers range in size (ram area) from 762 by 610 mm (30 by 24 in.) to 3.05 by 3.05 m (120 by 120 in.), with impact energies ranging from 8.9 to 134 kJ (6,600 to 99,000 ft·lbf). Ram dimensions and other pertinent details concerning these hammers can be found in the article "Hammers and Presses for Forging" in *Metalworking: Bulk Forming*, Volume 14A, *ASM Handbook*, 2005.

Planishing hammers are used to supplement drop hammer forming. These are fast-operating air-driven or motor-driven machines that are generally used for low-production operations to form dual-curvature surfaces. They are also used to planish welds and to smooth out wrinkles or other imperfections in drawn or drop hammer formed parts.

## Tooling

Dies for drop hammer forming are usually made by casting metals such as kirkite, which is a zinc-aluminum alloy, for rapid production of press tooling. These dies can be rapidly produced; are more economical than permanent dies; can be melted and recast; and can be reinforced at selected points of wear by facing with harder material, such as tool steel, for long production runs (Ref 2).

Normally, drop hammer forming is accomplished without the benefit of holddown. The metal is slowly forced into shape by controlling the impact of the blows. In many instances, it is necessary to use two- or three-stage dies, supplemental equipment, and hard forming, such as a bumping hammer or wooden mallet, to remove wrinkles, and so on.

To successfully complete forming operations, another aid that may be necessary is to anneal

material between die stages and intermediately for single-stage die forming.

Parts should be cleaned prior to annealing to protect the finish. Care should be taken to remove all traces of zinc that may be picked up from kirkite forming dies, because failure to remove the zinc will result in penetration of the steel (stainless) when treated and will cause cracking (Ref 2).

**Tool Materials.** Dies are cast from zinc alloy (Zn-4Al-3.5Cu-0.04 Mg), aluminum alloy, beryllium copper, ductile iron, or steel. The wide use of zinc alloy as a die material stems from the ease of casting it close to the final shape desired. Its low melting point (380.5 °C, or 717 °F) is also advantageous. All dies, regardless of die material, are polished.

Punches are usually made of lead or a low-melting alloy, although zinc or a reinforced plastic can also be used. The sharpness of the contours to be formed, the production quantity, and the desired accuracy primarily govern the choice of punch material. Lead has the advantage of not having to be cast accurately to shape, because it deforms to assume the shape of the die during the first forming trial with a blank.

**Rubber Padding.** In some drop hammer forming, both a working (roughing) punch and a coining (finishing) punch are used. When the working punch becomes excessively worn, it is replaced by the coining punch, and a new coining punch is prepared. Another method of achieving the same results with one punch is to use 3.2 to 25 mm (1/8 to 1 in.) thick rubber pads. Rubber that is suitable for this purpose should have a hardness of durometer A 60 to 90. In some cases, soft semicured rubber is used. In the

positioning of pads for a particular part (Fig. 3), the maximum thickness of rubber is situated where the greatest amount of pressure is to be applied in the initial forming. As forming progresses, the thickness of the rubber is reduced by removing one or more of the pads after each impact.

**Trapped Rubber Forming.** Drop hammer forming using trapped rubber dies is a process derived from the Guerin process, which is today (2005) synonymous with the term *rubber-pad forming* (see the article "Rubber-Pad Forming and Hydroforming" in this Volume). Both the Guerin and Marform (which is a refinement of the Guerin process) processes use hydraulic pressure instead of a drop hammer as the forming force. The trapped-rubber process using a drop hammer is used extensively by the aerospace and aircraft industries to fabricate sheet metal parts such as instrument panels, tank sections, air frames, stabilizer tips, air ducts, and doors made of aluminum alloys, titanium alloys, and stainless steels.

The drop hammer used in the trapped-rubber process offers several advantages over the hydraulic press used in the Guerin and Marform processes:

- Develops greater force (up to 44 MN, or 5000 tonf) per unit of applied energy in shorter time and at less cost
- Minimizes springback as a result of dynamic application of force
- Reduces tendency of material to wrinkle due to better material flow
- Reduces amount of hand finishing required due to dynamic application of pressure

Fig. 2 Schematic of an air-actuated power-drop hammer equipped for drop hammer forming

Fig. 3 Smoothly contoured stainless steel part that was hammer formed in a die with a peripheral trap for holddown. Dimensions given in inches

## Lubricants

Lubricants are used in drop hammer forming to facilitate deformation by reducing friction and minimizing galling and sticking, and to preserve or improve surface finish. Selection of a lubricant depends primarily on the type of work metal, the forming temperature, the severity of forming, and the subsequent processing. Recommendations for lubricants used with steels and with aluminum, magnesium, and titanium alloys are given in the sections of this article that deal with the processing of those metals.

## Blank Preparation

The blanks for drop hammer forming are generally rectangular and are prepared by shearing. The blank should be large enough to yield a part with a flange 50 to 75 mm (2 to 3 in.) wide in order to facilitate drawing of the metal during forming. When multistage forming is used, the part can be trimmed to provide a flange not less than 13 mm ( $1/2$  in.) wide for the final forming stage.

Sheared edges are generally satisfactory for drop hammer forming, because the wide flange permits some cracking in the flange area without harming the part. The blank should be deburred to avoid possible damage to the tooling.

## Drop Hammer Coining

Tableware, coins, and a variety of decorative items produced in copper alloys, stainless steel, sterling silver, and other metals are commonly coined by the drop hammer process. Processing details and production examples of drop hammer coining are given in the article "Coining" in *Metalworking: Bulk Forming*, Volume 14A, *ASM Handbook*, 2005.

## Multistage Forming

With the drop hammer process, complicated parts can be formed by means of a single die and punch. However, when a large quantity of a particular part is required, it is common practice to adopt a multistage forming technique, employing several sets of dies and punches. The forming operation in any one stage is less severe than if the part were formed in a single operation. Metals that work harden appreciably are usually annealed after each operation, unless a suitable die sequence eliminates the need for annealing.

Unless contact of the work metal with lead is undesirable, the number of stage dies can be kept at a minimum by using lead pads to reduce the depth of the die cavity. Lead can be poured into the die, or lead sheet can be laid in the bottom of the recess, to the desired height; the lead is then

formed to contour by a heavy blow of the punch. After the part has been preformed with the padded die, the pad is removed, and the part is then formed to the full depth of the die.

## Control of Buckling

Forming a deeply recessed part in thin sheet by any conventional method usually requires a high holddown force in order to prevent buckling. In drop hammer forming, the holddown action is restricted to the end of the stroke. Therefore, buckles are free to form during most of the stroke. The holddown pressure takes effect when the punch contacts the top of the wrinkles formed in the flange and rapidly increases until the die is bottomed. The wrinkles can be removed only at the end of the stroke and only if they are not too deep.

**Multistage Processing.** To avoid the formation of wrinkles that are too deep to be removed in the late stages of the stroke, the forming process is divided into several forming stages. The wrinkles formed in each stage are slight and can be eliminated at the end of the stroke or, if necessary, by manual hammering. To provide adequate holddown action at the end of each operation, it is common practice to use stage dies with surfaces that extend slightly beyond the trim line and to use punches equipped with suitable beads or traps.

**Holddown for Deep Parts.** To form deep parts, a series of plywood or metal holddown rings can be used; one ring is removed after each blow. These rings usually vary in thickness from 6.4 to 25 mm ( $1/4$  to 1 in.). The desired metal flow can be approached during the early stages of forming by using a blank that is considerably larger than that required to form the part. The excess metal is trimmed off after several blows. The stiffness of the oversized blank prevents draw-in and therefore induces stretching, which counteracts the tendency toward buckling. The die for a part with a deep recess must be designed with a horizontal surface to accommodate beading.

## Processing of Steels

Carbon and low-alloy steels containing less than 0.30% C are the most easily formed by the drop hammer process. Higher carbon content decreases formability and promotes cracking. Although lead additions do not adversely affect the formability of steel, the sulfur additions that are characteristic of resulfurized free-machining steels promote susceptibility to cracking. All carbon and low-alloy steels require full annealing for satisfactory drop hammer forming.

Stainless steels that are extensively formed by the drop hammer process include AISI types 302, 304, 305, 321, and 347. The common types of corrosion-resistant steel used for drop hammer

forming include 301, 302, 304, 305, and stabilized grades 321 and 347 (Ref 2). Type 301 work hardens more rapidly and is subject to strain cracking. It is possible to form some types (301 and 302) in quarter- and half-hard condition. However, the severity of the forming operation must be reduced to compensate for the prehardened material. For severe drop hammer forming, grades containing not less than 10% Ni (and preferably approximately 12%) should be selected in order to minimize cracking. The condition of material for the best forming should be the fully annealed (solution-treated) condition.

**Sheet Thickness.** The drop hammer forming of steel sheet (particularly stainless steel sheet) less than 0.46 mm (0.018 in.) thick is impractical, because of wrinkling and the difficulties encountered in attempting to planish the wrinkles. The most common range of steel sheet thickness for drop hammer formed parts is 0.61 to 1.6 mm (0.024 to 0.063 in.). Thicknesses up to 1.98 mm (0.078 in.) have been hammer formed.

**Tool Materials.** Cast zinc alloy is the most widely used die material for the drop hammer forming of carbon, low-alloy, and stainless steels. Alloy cast iron dies are substituted when a large quantity of parts is required. Inserts of an air-hardening tool steel can be used in order to increase the life of dies with sharp fillets and corners.

Punches are made of either zinc alloy or cast iron, and are ground to size. A zinc alloy punch, cast directly into the die, can be used for shallow parts, but it may be undersized (because of shrinkage upon cooling) if the part contains large cavities. Lead punches are also extensively used, although they are easily distorted when used to form steels. Punch life can be considerably increased by facing the punch with an untrimmed finish-formed steel part.

**Lubricants.** When zinc alloy dies and zinc alloy or lead punches are employed, many steel parts can be formed without a lubricant. Harder tool materials or more severe forming may require the use of a light lubricant, such as SAE 10 or SAE 30 mineral oil.

**Precautions for Stainless Steels.** Stainless steels, especially the austenitic grades, work harden more than the carbon and low-alloy steels that are suitable for hammer forming. In the cold forming of stainless steel, it is necessary to stretch the metal, rather than allow it to draw into the die. Stretching prevents the formation of wrinkles that are difficult to eliminate. By means of stretching, quarter-hard and even half-hard types 301 and 302 can be drop hammer formed, although only to a very limited extent. Part configuration must be simple and of only moderate depth; otherwise, wrinkles (in a shallow part) or distortion (in a complex shape) will occur. Although it is preferable that the part be made in a single die with a single blow, some commercial quarter-hard parts have required as many as three or four blows for successful forming.

When moderately complex parts are formed in a drop hammer in several stages, it is advisable to consider intermediate annealing in order to offset the effects of work hardening. It is not necessary to pickle after each annealing treatment (provided scaling is not too heavy), except before the finish-forming operation and after the final annealing treatment. If the part is formed in zinc alloy dies, any adhering zinc particles must be removed by pickling or by treatment in a fused salt bath (caustic soda) before annealing treatments (both intermediate and final). This requirement is most important for parts that are to be welded or that will be exposed to elevated-temperature service. Failure to remove the zinc may result in cracking.

**Springback.** Carbon and alloy steel parts, and especially stainless steel parts, having large radii and smooth contours are more difficult to maintain in desired shape than parts with relatively sharp radii, because of the greater springback under these conditions. Common practice is to compensate for this springback from the desired contour by trial and error. If this method is not successful, the part must be distorted elastically upon assembly, that is, sprung into the final shape.

Parts with reverse contours (saddleback parts) are extremely difficult to form without excessive wrinkling.

**Limits in Deep Recessing.** When deeply recessed parts are to be formed in a drop hammer, the recesses are limited in both depth and contour. With a single die, a cup-shaped or dome-shaped part can be formed to a limiting depth of 60 to 70% of that obtainable by means of double-action dies. Square and rectangular steel boxes (even shallow ones) require a minimum corner radius of 6.4 mm ( $\frac{1}{4}$  in.) or five times the metal thickness, whichever is larger. For deeper boxes, progressively larger corner radii are necessary, and these minimum radii apply to boxes of any width.

## Processing of Aluminum Alloys

The drop hammer forming of aluminum alloys is most suitable for limited production runs that do not warrant expensive tooling. The process is often used for parts, such as aircraft components, that undergo frequent design changes. Some forming applications also involve coining and embossing. The article "Forming of Aluminum Alloys" in this Volume contains more information on the forming of aluminum alloy sheet.

The drop hammer can be used to form deep pan-shaped and beaded-type parts. Kirksite with a plastic surface insert is satisfactory for male and female dies (Ref 2). The surface of kirksite dies used without a plastic insert should be smooth to prevent galling and scratching of the aluminum surface. When forming deep pans and complicated shaped parts, it is often necessary to use drawings rings, pads, or two- to three-stage dies. An intermediate anneal is

sometimes used to relieve the hardened condition (cold work) resulting from the forming operation.

**Work Metal.** Annealed tempers of all aluminum alloys are the most suitable for hammer forming. Intermediate work-hardened tempers of the non-heat-treatable alloys are often used for channel shapes and shallow embossed panels.

Heat-treatable alloys are often partly formed in the annealed condition. The part is then solution heat treated, quenched, restruck to size, and artificially aged. Restriking is also necessary to remove distortion caused by quenching. Drop hammer forming can be done on freshly quenched alloys immediately after quenching, or it can be done later if the alloys are refrigerated to prevent aging.

**Sheet Thickness.** Under comparable conditions, with the same equipment and with the same thickness of sheet, aluminum wrinkles more easily than steel under a drop hammer. To obtain results comparable to those obtained with steel, aluminum alloy sheet should be at least 40% thicker than the steel, or preferably in the approximate thickness range of 0.86 to 3.18 mm (0.034 to 0.125 in.).

**Equipment and Tool Materials.** Aluminum alloys are drop hammer formed in gravity-drop, power-drop, and planishing hammers. Dies are cast from aluminum, zinc alloy, iron, or steel. Dies for high production are usually cast in iron or steel. All dies are polished. Most punches are made of lead or a low-melting alloy, although zinc alloy or reinforced plastic can also be used. The softer punch materials have the advantage of deforming readily to assume the shape of the die during forming trials. When planishing hammers are used, the preferred tool material is hardened, polished tool steel.

**Forming Characteristics.** Annealed aluminum alloys are readily formed under the drop hammer. Simple components can often be produced by a single blow. Deep shapes require extreme care in blank development and die design. Blankholders are not used; therefore, wrinkles are difficult to avoid, especially when thin sheet is being formed.

## Processing of Magnesium Alloys

The drop hammer forming of magnesium alloys is performed on preheated sheet in heated dies. This procedure is suited to the production of formed parts having shallow depths and asymmetrical shapes and to parts for which special springback control is required.

**Work Metal.** Magnesium sheet alloys in the annealed condition are preferred for drop hammer forming. The ideal sheet thickness for forming is 3.2 mm ( $\frac{1}{8}$  in.), and the part should be designed so as to be formable in six stages or fewer. For sheet thinner than 3.2 mm ( $\frac{1}{8}$  in.), ten stages or fewer are recommended.

**Equipment and Tool Materials.** Both gravity-drop and power-drop hammers are sui-

table for the forming of magnesium alloys. Zinc alloy is the preferred punch and die material, although lead punches are sometimes used for production runs of not more than 50 pieces. When lead comes in contact with magnesium sheet, there is danger of lead pickup, which can cause corrosion of the sheet. Although lead pickup may occur at room temperature, it is more likely to occur at the elevated temperatures at which magnesium alloys are formed. Therefore, if lead pickup cannot be tolerated or if the production run exceeds 50 pieces, either zinc alloy or cast iron can be substituted for lead.

**Lubricants.** Vegetable-lecithin oils provide good lubrication at temperatures to 260 °C (500 °F). Suspensions of colloidal graphite may have to be used if temperatures are to exceed 260 °C (500 °F). However, these suspensions are more difficult to remove when parts are cleaned after forming.

**Preheating.** Magnesium alloy parts are usually formed at temperatures of 230 to 260 °C (450 to 500 °F), depending on the alloy (see the article "Forming of Magnesium Alloys" in this Volume). Heating times are 5 min per stage for sheet up to approximately 1.29 mm (0.051 in.) thick, and up to 9 min per stage for thicker sheet (up to 3.2 mm, or 0.125 in.).

The oven used to heat the parts between stages should be situated near the drop hammer; the decrease in temperature during transfer from the oven to the hammer will range from 17 to 25 °C (30 to 45 °F) in 5 s. The dies can be heated by placing them in an oven located near the hammer, and they can then be kept at temperature with ring burners or torches during the forming of the part.

Small dies can be anchored to an electrically heated cast iron platen installed on the hammer bed, but this method is impractical for large dies. The punch and die can also be heated by electric elements or by a heat-transfer fluid. The working temperatures should not exceed those recommended.

**Rubber pads** can be used in the initial forming operation. At 230 °C (450 °F), the reduction obtainable with rubber staging is approximately 10%. Special types of rubber are available for forming at temperatures to 315 °C (600 °F). The rubber pads are removed before the final blow is delivered to set the material.

**Springback.** One advantage of the elevated temperatures used in the drop hammer forming of magnesium is the marked reduction or total elimination of springback, provided the maximum practical temperatures are always employed. The rate of the deformation is important in drop hammer forming and must be carefully controlled upon severe drawing or when material in the hard (H24) temper is being formed. The rate of deformation can be controlled by the operator, although not to close limits. Parts that require relatively severe forming can be started by allowing the punch to descend slowly into the die and by using subsequent strikes to set the material.

**Dimensional Tolerances.** Tolerances of  $\pm 0.76$  mm ( $\pm 0.03$  in.) have been held in the production of magnesium parts. When close tolerances are important, press forming is usually the preferred method for the forming of magnesium parts.

## Processing of Titanium Alloys

Various titanium sheet alloys have been formed by the drop hammer process, including Ti-13V-11Cr-3Al, Ti-8Al-1Mo-1V, Ti-6Al-4V, and Ti-5Al-2.5Sn. In general, the alloys containing aluminum as the principal alloying element are the most difficult to form. The minimum thickness of titanium sheet for hammer-formed parts is approximately 0.64 mm (0.025 in.).

Drop hammer forming of titanium has been very successful and has been accomplished at both room and elevated temperatures. Kirksite is satisfactory for male and female dies where only a few parts are required. If long runs are to be made, ductile iron or laminated steel dies are usually necessary. In drop hammer forming, the best results are usually by warming the female die to a temperature of 425 to 540 °C (800 to 1000 °F) for 10 to 15 min (Ref 2). The part is then struck and set in the die. Usually, a stress-relief operation at 540 °C (1000 °F) for 20 min is necessary, then a restrike operation. In most instances, a finished part requiring no handwork is obtained.

Parts should be cleaned prior to annealing to protect the finish. Care should be taken to remove all traces of zinc that may be picked up from kirksite forming dies, because failure to remove the zinc will result in penetration of the steel (stainless) when treated and will cause cracking (Ref 2).

**Tool Materials.** Contact between titanium and low-melting tool materials, such as zinc alloy or lead, should be avoided—particularly when the titanium is formed at elevated temperature or must be heat treated after forming. When these tool materials are used, contact with the workpiece can be avoided by capping the

punch and die with sheet steel, stainless steel, or a nickel-base alloy. The choice of capping material depends on the tool life desired. The longest tool life is obtained by capping with nickel alloy sheet such as alloy 600 (UNS N06600) in thicknesses of 0.64 to 0.81 mm (0.025 to 0.032 in.).

In general, steel and ductile iron dies are used when the tooling must be heated above 205 °C (400 °F). Preheating of both the work metal and the tooling is not uncommon.

**Rubber Pads.** High-temperature rubber pads are used both in preforming operations before the final strike and as electrical insulators to prevent current loss to the tooling when the work metal blank is heated by the electrical-resistance method.

**Lubricants** used in the drop hammer forming of titanium should be nonchlorinated. Extreme-pressure oils and both pigmented and non-pigmented drawing compounds are used in most operations.

**Preheating Tools and Blanks.** Difficult titanium parts are formed at elevated temperature (see the article "Forming of Titanium and Titanium Alloys" in this Volume for recommendations and precautions). Thermal expansion of the blank and the tooling must be considered. If the tooling is not preheated, the amount it expands will depend on the length of time it is in contact

with the blank. The allowance for thermal expansion used in the design of tooling for titanium is 0.006 mm/mm (0.006 in./in.) for a forming temperature of 540 °C (1000 °F). The allowance for expansion of circular or elliptical parts should be made radially, not peripherally. When hot sizing is to follow forming, the drop hammer tooling is usually made to net dimensions without consideration of thermal expansion.

**Formability versus Temperature.** Variation of the drop hammer formability index for two titanium alloys with temperature is given in Fig. 4. It is evident from the curves that significant increases in formability can be achieved at temperatures above 540 °C (1000 °F).

## Drop Hammer Forming Limits

The severity of permissible deformation in drop hammer forming is limited both by geometrical considerations and by the properties of the work metal. The forming limits can be predicted by considering parts of interest as variations of beaded panels. For parts characterized in this way, the critical geometrical factors are the bead radius,  $r$ , the spacing between beads,  $s$ , and the thickness of the work metal,  $t$  (Fig. 5).

Two of the forming limits depend entirely on dimensional relations and are the same for all materials; the ratio of the bead radius,  $r$ , to bead spacing must lie between 0.35 and 0.06. The lower formability limit is controlled by the necessity of producing uniform stretching and avoiding excessive springback. If the  $r/s$  ratio is too small, there will be greater localized stretching at the nose of the punch.

Within the limits set for all materials by the  $r/s$  ratio, success or failure in forming beaded panels depends on the ratio of the bead radius to the sheet thickness ( $r/t$ ) and on the ductility of the work metal. The part will split if the necessary amount of stretching exceeds the ductility available in the material. The splitting limit can be predicted from elongation in a 12.7 mm (0.5 in.) gage length in tension tests at the temperature of interest.

Formability limits for two titanium alloys are plotted in Fig. 5. Both charts show the marked improvements in formability resulting from the better elongation values at elevated temperature.

Fig. 4 Effect of forming temperature on the drop hammer formability of two titanium alloys

Fig. 5 Formability limits of beaded titanium alloy panels at room temperature and at elevated temperature

# Thermal Forming of Sheet and Plate

Alan Male, University of Kentucky

THERMAL FORMING OF METALS refers to the development of permanent deformation without the application of external mechanical forces. It is based on the fundamental physical principle that most metals expand when heated and contract when cooled. If the expansion is limited in two dimensions, compressive stresses build up and result in localized plastic deformation if the temperature is sufficiently high. This plastic deformation then occurs in the third dimension. Upon cooling, the deformed material does not return to its original dimension, thus imparting a shape change upon the whole component. It is important, of course, that no melting is allowed to take place.

Historically, thermal forming has been used for flame straightening of structures and weldments, and for bending of plates for ship construction. As its name implies, a gas flame was used as the means of heating. More recently, interest has been revived in such processing because of the development of laser technology for heating.

Until recently, industrial application of thermal forming techniques using gas flames has been based largely on empiricism, and the ensuing results have depended principally on the skill and experience of the operators performing the process. Considerable research has been conducted with the aim of providing greater understanding and quantification of the technology. An excellent detailed status of this research may be found in the proceedings of an international workshop (Ref 1). Today, thermal forming is developing as a highly sophisticated potential manufacturing technology. Well-defined and closely controllable heat sources such as laser beams and plasma jets allow for the precise and reproducible heating of a very localized area of material and thus allow the possibility of automation. Additionally, the process is contributing to the development of rapid prototyping technologies. Furthermore, it provides other non-traditional possibilities, such as in-use repair or modification of sheet metal components.

## Energy Sources

Thermal forming relies on the availability of a localized and controllable energy source to produce local heating of the material to be formed.

In fact, four energy sources have been used for thermal forming: an electric induction coil, a gas flame, a plasma torch, and a laser beam.

The gas flame is usually from a handheld oxyacetylene torch and is obviously the least controllable and reproducible method of heating. Equipment for such heating is very inexpensive. Details of such torches can be found in many welding manuals, including Volume 6 of *ASM Handbook*, and is not further elaborated here.

A high-frequency electric induction coil is probably the most efficient of the available energy sources because the heat is created directly in the metal by the induced eddy currents. The higher the frequency used, the shallower the depth of heating occurring. As will be apparent later, this may be an advantage in promoting faster forming.

Light amplification by stimulated emission of radiation (laser) provides a beam of visible light of significant energy. It may be used for rapidly heating metallic materials provided the energy of the beam can be transferred to the material by "coupling" rather than being reflected away. Coupling is usually accomplished by use of a spray coating of graphite on the workpiece surface to promote heat absorption. This must be periodically reapplied because of its gradual oxidation during multiple exposures. It is generally accepted that the overall energy transfer ratio of laser systems into the workpiece material is rather low ( $<10\%$ ).

Lasers are available in a variety of types and power levels. Low power lasers of the neodymium-yttrium (Nd-YAG) type may use fiber-optic beam delivery systems. High-power CO<sub>2</sub> lasers require water-cooled copper mirror systems and are expensive. All laser systems require extensive safety precautions because of the potential for damaging stray reflections. Further details of laser systems may be found in Volume 6 of *ASM Handbook*.

Plasma arc systems are less expensive than most high-power laser systems (usually  $<10\%$ ) and are readily available. To avoid the need for making electrical connection to the workpiece, a nontransferred plasma arc torch system is preferred. Although normal safety precautions must be strictly adhered to, they are normally safer than laser systems. The overall energy transfer ratio is generally  $>85\%$ . Details of plasma arc torches and systems may be found in Volume 6

of *ASM Handbook* and in the article "Electric Arc Cutting" in this Volume.

## The Basic Process

Modern thermal processing using a laser has been pioneered in Poland (Ref 2, 3) and in Germany (Ref 4, 5). More recently, the concept of using a plasma arc heat source was introduced in the United States (Ref 6, 7). With the exception of the heat source details, the processes are similar in concept.

The basic process for a plasma arc heat source is illustrated in Fig. 1. A cooling jet (cooling stream 1), usually of CO<sub>2</sub> gas, is positioned on the back of the workpiece directly opposite the heat source. Occasionally, and more normally with a laser system, an alternate cooling jet (cooling stream 2) is located behind the heat source.

The amount of deformation achieved with each thermal scan is limited. Thus, a multiple of repeated scans are required to develop significant amounts of bending or of change in shape.

## Mechanisms of Forming

**Bending toward the heat source** is a term used to describe a metal sheet bending process in which there is a concave hinge on the bending straight line. During the heating process, the heat input and cooling stream 1 (Fig. 1) are combined to make the upper part of the sheet metal section (zone S<sub>1</sub>, Fig. 2) reach its plastic state and allow the lower part (zone S<sub>2</sub>) to maintain its elastic

Fig. 1 Schematic of thermal forming of metal sheet

state. The material in zone  $S_1$  expands because of being heated. However, because the zone  $S_2$  retains its stiffness, it inhibits free expansion within  $S_2$ . The partial outflow will occur in zone  $S_1$ , as shown in Fig. 2. Stresses in the  $S_1$  zone are compressive because the expansion of these areas is restrained by surrounding metal that is at lower temperature. The compressive stresses will reach the yield level of the metal at that temperature, and plastic deformation will be produced in zone  $S_1$ . Because zone  $S_2$  is in an elastic state, the workpiece becomes bent away from the heat source by an angle  $\alpha_1$ . The combination of the heat source input and cooling stream 1 from the back side can control the temperature and size of zones  $S_1$  and  $S_2$ . The cooling stream 2 that follows the heat source decreases the temperature of zone  $S_1$  and produces a contraction in the previously heated and compressed zone  $S_1$ . As the metal in the heated and cooled zone tries to shrink, tensile stresses are induced in zone  $S_1$ . This manifests itself by a bend toward the heat source at an angle  $\alpha_2$ . Because the yield stress at low temperature is higher than that at high temperature, the tensile stress produced during cooling will result in a relatively greater shrinkage. As a result of these two processes (the heating and the cooling), a permanent deformation appears so as to produce a concave hinge on the heated side and a permanent bending angle of  $\alpha_3 = \alpha_2 - \alpha_1$ , as shown in Fig. 3.

Fig. 2 Sectional view of a heating phase of the plate to be bent

Fig. 3 The deformation of metal sheet during heating and cooling processes

**Bending Away from the Heat Source** refers to metal sheet bending such that the surface being heated exhibits a convex hinge. The heating and cooling process along  $i-i$  is very close to that shown in Fig. 1. There is, however, the difference that the energy beam is wider when compared with the sheet thickness and the total thickness is heated thoroughly (Fig. 4a). The cooling stream 2 following the heat source is at a greater distance behind (or does not use a front cooling stream) and the flow rate of cooling stream 1 is much lower. Because the heated surface of the sheet is away from its neutral axis, a bending moment is produced. The metal near the heat source is heated to higher temperatures than the metal away from the heat source. The hotter metal expands and the sheet bends away from the plasma. Additionally, the total thickness of the sheet is heated thoroughly, a relatively great plastic strain is produced by the thermal cycle and after cooling, the convex shape is maintained, as shown in Fig. 4b.

A hollow box component formed using both of these bending methods is shown in Fig. 5.

**Other Deformation Modes.** Combination of the aforementioned two concepts can be used together with particular workpiece geometries to achieve different modes of deformation. For example, the local diameters of tubular workpieces can be either increased or decreased, or

the wall thickness increased or decreased at will (Ref 8), as depicted in Fig. 6 and 7.

### Effect of Process Parameters on Forming

Any process parameter that is likely to raise the workpiece surface temperature to the highest level, without causing melting or other adverse metallurgical effect, and to do it as rapidly as possible will generate the maximum amount of bending for each thermal scan (Ref 9). With a laser beam, this refers to the laser power, beam spot size, rate of travel over the workpiece surface, and the efficacy of the coupling medium on the surface.

For plasma forming, the diameter of the plasma jet increases with distance from the orifice. Thus, as the distance between a plasma torch nozzle and the workpiece surface increases, for a given travel speed, the temperature developed in the workpiece surface is reduced, thus resulting in a lower rate of forming (Ref 10), as shown in Fig. 8. Similarly, as the travel speed is increased, the workpiece surface temperature is reduced, also resulting in a lower rate of forming (Fig. 9). Other parameters will also control the temperature of the workpiece surface. A smaller plasma nozzle diameter and/or an increased plasma gas flow rate will increase

work surface temperatures and promote higher forming rates.

## Effect of Material Parameters on Forming

As can be seen from the mechanisms of bending outlined earlier, any material parameter that affects the amount of plastic upsetting occurring during the heating cycle will control the amount of shape change (bending) upon cooling. These parameters are likely to be material thickness, thermal expansion coefficient, thermal conductivity, and detailed effects of temperature on the plasticity characteristics of the material. In general terms, any factors likely to affect the temperature gradient between the top (heated) surface of the workpiece and the bottom (cooled) surface, will affect the degree of thermal forming achieved.

Bending trials were reported (Ref 11) using four different materials of thickness 0.8 mm (0.04 in.): stainless steel, mild steel, copper, and aluminum. The results are given in Fig. 10 and show that, in general, under the forming condi-

tions used, the materials behave somewhat similarly with the bend angle increasing with the cumulative increase in the number of plasma scans accomplished. Note the small degree of bending that can be induced with the copper material as compared with the other materials. Figure 11 shows the bend angle cumulatively generated by 12 plasma scans at various travel speeds for the four different materials, but plotted as a function of the material thermal conductivity. This indicates the large effect of that physical parameter on the bending behavior of the sheet material.

This observation is in accord with the concept that the achievement of a large thermal gradient between the front (heated) side and the back (cooled) side of the sheet material would promote more localized thermal expansion and associated plastic deformation, which would enhance the force available to cause bending upon subsequent cooling. It is easier to develop large thermal gradients in materials with relatively low thermal conductivities such as stainless steel. Indeed, one must be careful with such materials because it is possible to induce surface melting under conditions where higher thermal conductivity, but lower melting temperature, materials do not suffer the same degradation.

As noted previously, the basic mechanism of bending sheet metal using a heat source is the plastic compression of the heated zone during heating and the support of the compressed zone during cooling by the surrounding material. Thus, the forming behavior should be similar regardless of the type of heat source, whether it be a laser beam or a plasma torch. For example, the work using plasma heating (Ref 10) strongly indicates that the thermal conductivity of the material has a significant effect on the bending behavior, depending on the particular process parameters used. On the other hand, the findings of a researcher (Ref 12) who conducted bending

experiments using a laser suggested that the thermal conductivity of the material had only a secondary effect on the bend angle. The apparent difference in findings may be due to the two widely differing regimes used in the two sets of experiments. The work in Ref 11 used a sheet thickness of 0.8 mm (0.04 in.) and heat source travel speeds of 2 to 8 mm/s (0.08 to 0.3 in./s), while Vollertsen (Ref 12) used sheet thicknesses of 1 to 7 mm (0.04 to 0.28 in.) and heat source travel speeds of 25 to 583 mm/s (1 to 23 in./s). Thus, according to the data shown in Fig. 11, Vollertsen's results could be compressed toward relatively low heat input rates producing low bend angles and therefore mask the thermal conductivity effect.

## Structure and Properties

It must be kept in mind that thermal forming is also a heat treatment operation by virtue of the thermal exposure. Simple or complex metallurgical changes are likely to occur, depending on the particular workpiece material. Mechanical property changes will occur as a result of these metallurgical changes. Limited increases were reported (Ref 13) in hardness in the bend region of AISI 304 stainless steel formed using a plasma torch. However, these increases were significantly less than what was found with conventional mechanical bending at room temperature. Other work by (Ref 10) evaluated the effect of plasma forming on the microstructure of both 304 stainless steel and mild steel. The 304 stainless steel has an austenitic structure over a wide temperature range, and no significant change in microstructure was observed after thermal forming. The mild steel, on the other hand, undergoes a phase transformation from ferrite to austenite on heating and the reverse on cooling. Thermal forming of this

**Fig. 13** Tube bend manufactured by laser forming (Ref 8)

material was found to cause considerable grain refinement in the areas most affected by the plasma heating. No associated data were reported for any mechanical property changes.

Other researchers (Ref 14) performed a microstructural investigation of laser forming of aluminum and aluminum alloys using optical and electron microscopy. Zones with different substructures were observed depending on processing parameters. The degree of substructural development could not be explained entirely by laser parameters and material characteristics. Hardness tests of laser-formed material indicated the existence of different zones depending on the specific material and heat treatment.

## Applications

For a number of years "flame straightening" has been used to both shape and straighten steel beams and girders. Indeed, it has been used for the in-situ repair and straightening of

damaged bridge structures (Ref 15). Line heating using gas flame torches has also been used for bending and for weld distortion removal in shipbuilding (Ref 16). Such applications rely exclusively on the experience and expertise of the operator.

Because of the potential for automation in producing three-dimensional sheet profiles, much research has been oriented toward analysis and control of the process—for example, the works of various researchers in Britain (Ref 17–20). However, functioning systems are not known to be available at the present time.

It must be stressed that this is an evolving area of technology with no known applications reduced to manufacturing practice. Some potential applications are shown in Fig. 12 to 14. On the other hand, Geiger, Vollertsen, and coworkers in Germany are developing applications in the electronics manufacturing area.

# Peen Forming

R. Kopp and J. Schulz, Institute of Metal Forming, Aachen University, Germany

**SHOT PEEN FORMING** is a manufacturing process in which local compressive residual stresses form thin sheet metals and structural components in one or more dimensions. It was developed out of blasting technologies that are better known, such as cleaning, finishing, and hardening blasting. During these blasting technologies, the elastic-plastic impacts of the shot medium onto the thin workpiece often unintentionally cause macroscopic deformations. Shot peen forming uses this normally undesirable phenomenon to specifically form sheet metal components.

The process is primarily used to manufacture large sheet metals and single components or components with a relatively small lot size. Such components are mainly used in the transportation industry, particularly in the aircraft and aerospace industries and in shipbuilding and carriage building, for example (Ref 1, 2).

The forming tool (the balls) can be used universally; that is, the manufacturing of individually formed dies is not necessary. This substantial tool cost reduction leads to high profitability in spite of the relatively long forming cycles according to the size of the component and the forming parameters. The cost advantage increases with decreasing lot size.

## Principle of the Process

**Fundamental Mechanisms.** Shot peen forming is a flexible pressure-forming process

**Fig. 1** Zones of influence in shot peen forming.  $F$ , force direction; 1, forming zone; 2, properties prior to forming; 3, properties after forming; 4, effective contact area; 5, tool (shot); 6, surface reactions; 7, shot peen forming machine; 8, factory. Source: Ref 3

that can be divided into eight influence zones (Fig. 1), according to Ref 3. The deformation mainly depends on the tool-workpiece contact area, the deformation zone, the tool, and the shot peening facility. The deformation zone of a single shot depends on the flow resistance of the material, that is, the resistance against being formed, and on the ball energy resulting from the ball mass and the ball velocity. Each shot causes a scallop-shaped deformation on the tool-workpiece contact surface.

Shot peen forming is based on the principle of changing the material state by locally effective inhomogeneous elastic-plastic deformation. With hardening peening, a deformation only occurs near the surface up to a depth of 200  $\mu\text{m}$ , depending on the shot medium, the material, and the parameters selected. Deformation occurring during shot peening can, however, affect thicker surface layers up to the entire cross section of the material. Because the hits of the shot medium or the individual balls onto the workpiece are partly plastic, the kinetic energy involved is transformed into elastic and plastic deformation of the workpiece.

Depending on the local plastic deformation depth of the material beneath each impact, it is possible to generate either a convex or a concave curvature.

**Convex Curvature.** During shot peening, the tool (the ball) transfers a part of its impulse onto the workpiece during the elastic-plastic impact. When the stress induced is higher than the flow stress of the workpiece material, the contact area is compressed and displaced perpendicular to the force direction. These deformations describe a radius around the ball impression zone, as illustrated in Fig. 2 for peening with and without the influence of friction.

A three-dimensional residual-stress and deformation state beneath the shot impact is produced. In the case of peening under frictional influences, the maximum radial strain is located at a certain depth, because the material flow, and thus the plastic deformation, is obstructed by friction between the ball and the surface of the workpiece.

When a large number of balls hits the workpiece, the material areas lying near the surface undergo a plastic elongation (Fig. 3). This plastic deformation reaches a maximum on the surface, while it is reduced with increasing depth (Ref 4).

The plastic elongation of the component surface implies elastic strains in the other layers of the material, leading to a convex bending of the peened material. The residual-stress distribution

**Fig. 2** Radial strains ( $\epsilon_r$ ) underneath a ball mark with and without friction ( $\mu$ ). (a) Without friction. (b) With friction.

**Fig. 3** Plastic deformation and elongation of the near-surface layers.  $\epsilon_r$ , radial strain;  $\sigma_{rs}$ , radial stress. Source: Ref 4

**Fig. 4** Principle of convex shot peen forming. Source: Ref 1

produced by this convex bending ensures a balance of forces and moments.

The residual-stress distribution shows residual compression stresses at the surface and residual tensile stresses at greater depths in the workpiece (Fig. 4).

The mechanism of convex forming takes place when shot peening causes only plastic deformation and elongation of a thin surface layer compared to the cross section of the peened workpiece. In this case, the workpiece is bent in the direction of the shot. An elementary model to describe this residual-stress distribution is contained in Ref 1.

**Concave Curvature.** Plastic deformation of the entire cross section generates a curvature in the direction of the force; the formed sheet metal will thus emerge concave. The depth of the

**Fig. 5** Strains in the cross section dependent on the shot velocity ( $v_B$ ). See text for description. Source: Ref 5

plastically deformed layer depends directly on the kinetic energy of the shot medium, which can be modified simply by changing the shot velocity. Figure 5 illustrates the relation between convex or concave curvature and the shot velocity (Ref 5).

At low shot velocities, a convex curvature is produced. The fiber on the top of the workpiece is plastically elongated. The balance of forces and moments induced leads to elastic compression at the bottom fiber. As the shot velocity increases, the neutral fiber initially located in the middle of the cross section moves to the bottom (a, b in Fig. 5). The maximum convex curvature is reached when the neutral fiber is on the bottom surface of the sheet metal (c). When the shot velocity is increased further, the bottom fiber will also be plastically elongated (d), but the plastic elongation is smaller below than above this fiber. Because all fibers of the cross section are now plastically elongated, there is no longer neutral fiber. At the inflection point of the curve, the plastic elongations on the top are as high as on the bottom (e). Despite being elongated, the workpiece remains flat. With even higher shot velocity, the plastic elongations are higher on the bottom than on the top surface (f); the curvature thus turns into a concave form.

To confirm this relation between curvature and shot velocity, tests were conducted with sample strips of the aluminum alloy AlMg<sub>3</sub> in the dimensions 250 by 100 mm<sup>2</sup> (Fig. 6). Moreover, the sheet metal thickness was varied (2, 3, and 4 mm). Shot peening tests were carried out using balls with a 6.4 mm diameter (injector-gravitation peening system). The distance between the nozzle and the sample was 200 mm, with a constant mass flow of 20 kg/min. Sample strips were shot peened sinusoidally, with a distance of 10 mm between peening traverses.

**Fig. 6** Curvature dependence on shot velocity. Alloy: AlMg<sub>3</sub>; workpiece geometry: 250×100 mm<sup>2</sup>. Source: Ref 5

**Strain rates** during shot peen forming are very high. For a rough estimate of local strain rates, the deformation zone beneath the shot impact is simplified to form an axisymmetric cylinder. Instead of homogeneous deformation resulting from a linear velocity distribution, however, the velocity field  $v_z(z)$  is assumed to be a squared function, according to Fig. 7, which must be consistent with the shot velocity conditions on the one hand and with the demand for constant volume on the other (Ref 6). The  $z$ -direction velocity,  $v_z(z)$ , is assumed to be a function of the distance  $z$  above the depth  $h_0$  (Fig. 7) such that:

$$v_z(z) = f(z^2) = -v_B \frac{z^2}{h^2}$$

where  $v_B$  is the velocity of the peen ball. Consequently, the strain rate for axisymmetric deformation is:

$$\dot{\epsilon}_z = \frac{\partial v_z}{\partial z} = -v_B \frac{2z}{h^2}$$

and, with constant volume:

$$\dot{\epsilon}_r = -\frac{\dot{\epsilon}_z}{2} = v_B \frac{z}{h^2}$$

As an example, using the parameters  $v_B = 18$  m/s and  $h_0 = 2.1$  mm, a ball impact would produce the following strain rates:

$$\dot{\epsilon}_z(z=h_0) = 17,140 \text{ s}^{-1}$$

$$\dot{\epsilon}_r(z=h_0) = 8570 \text{ s}^{-1}$$

## Simulation of Shot Peen Forming

**Basic Considerations.** The number of balls used for shot peen forming of large sheet metal components is  $10^5$  to  $10^6$ . Interactions occur between the balls by direct contact and scatter. Modeling is difficult because of the fact that the actual forming process can take several minutes or even hours, whereas the individual ball hits occur within a period of  $10^{-4}$  to  $10^{-5}$  s. Due to the large dimensions of the components, a very rough mesh is required. To be able to describe the deformation zone beneath each shot impact up to a depth of approximately  $10^{-1}$  mm and in order to determine the stress gradients in the cross section, however, the length of the element edges should be no longer than  $10^{-2}$  to  $10^{-1}$  mm. Simplified material laws, with the material considered as a continuum, are usually used to describe the material behavior. In addition, the fact that the initial material may contain inhomogeneities (due to the forming history of the material) may also have an influence on the residual-stress distribution induced by shot peen forming. Moreover, elastic stress caused by clamping or preloading influences the results to a great extent. Also, the flow curve description has to take into account the high strain rates of  $10^3$  to  $10^4 \text{ s}^{-1}$ , which makes it difficult to determine suitable material laws. Nevertheless, modern

finite element modeling simulation techniques can contribute to a better understanding of the mechanisms operating during shot peening.

**Single Impact.** Simulations were carried out with different shot velocities and ball dimensions according to Fig. 8 (Ref 5). For the simulations, flow curves for the material AlMg<sub>3</sub> were used, which are valid for a range of strain rates from  $0.001 \text{ s}^{-1}$  to  $10,000 \text{ s}^{-1}$ . Figure 9 shows the average radial elongation for each layer as a typical measure for a larger area in the radial direction. The average value of the radial strain ( $\bar{\epsilon}_r$ ) in the radial direction (Ref 7) over a distance  $R$  (Fig. 9) is:

$$\bar{\epsilon}_r = \frac{1}{R} \int_0^R \epsilon_r dr = \frac{\sum_i \epsilon_{r,i}}{i}$$

Figure 10 shows the average radial strain distribution over the cross section.

After a shot impact, a specific area on the top surface is elongated. As mentioned previously, at low shot velocities, the fibers at the bottom are compressed. While being high at low velocities, these compressions are reduced and become *elongations* with increasing shot velocity. At the highest shot-velocity of 20 m/s, the bottom side of the component is stretched. This is due to the fact that the short-term stretching of the fibers is higher in lower layers of the cross section than

**Fig. 9** Determination of average radial strains

**Fig. 10** Average radial strains in the cross section after a single impact. Source: Ref 5

in upper layers. This elongation on the bottom side produced by the shot impact dynamics leads to a concave curvature of the component.

**Multiple Impacts.** Multiple-impact peening simulations are limited by local geometry and time discretization. When simulating a single impact whose deformation is very local, the mesh chosen for the impact zone has to be very fine in order to simulate the real processes occurring at the contact surface and in the deformation zone.

Because ball impacts have an effect not only in one location but can influence the entire work-piece surface, it is often necessary to have a fine mesh for the entire component. Also, process time discretization has to be fine, with the deformation during each impact calculated in several steps due to the nonlinearity of the process. The chronological order of the impacts has to be simulated as well, so that it is impossible to calculate all impacts simultaneously. That is the reason why correct simulation requires a large number of steps for a large model, entailing a great deal of computation and memory. Figure 11 represents a simulation using 210 balls.

## Equipment/Tooling

**Peen forming facilities** were developed as a spin-off of the first sandblasting facilities designed for cleaning. The first peening facilities were simple manual blasting facilities, still widely used today, followed by the first automatic peen forming machines. Nowadays, peen forming

facilities can be distinguished by the way the shot medium is accelerated (Ref 8). The most important machines are illustrated schematically in Fig. 12.

**Centrifugal wheel spinning systems** (Fig. 12a) do not use pressure to accelerate the shot medium. The balls are accelerated directly, that is, without any other medium, by the centrifugal force of the spinner. This type is used for a high mass per area and large surfaces to be peened.

**The air pressure system** (Fig. 12b) uses compressed air to accelerate the shot medium. The compressed air and the shot medium are merged below the reservoir, then transported to the nozzle through a common hose. Shot velocities may be much higher than with spinner peening facilities. The shot medium is more concentrated so that it can be used more effectively.

**The injector peening system** (Fig. 12c) uses two separate hoses leading to the peening nozzle, one for the compressed air and one for the shot medium. Acceleration of the shot medium does not take place before it is merged with the compressed air in the peening nozzle. The shot medium is sucked into the nozzle by the low pressure generated. Injector peening machines are not very expensive and can be easily automated because the shot medium does not need any transport or conveying facilities.

**The injector-gravitation peening process** (Fig. 12d) is slightly more complex. It also contains two separate hoses designed for the compressed air and the shot medium. However, the shot medium is not sucked from the reservoir below but transported through a conveying facility to a shot medium supply tank above the peening cubicle. The shot medium falls under gravitational forces through a pipe into the peening nozzle, where acceleration takes place by compressed air. The main advantage of this design is the continuous, smooth exit of the shot medium with relatively low peening pressure.

**Shot Properties.** In contrast to hardening blasting, the most suitable shot medium for shot peen forming consists of round balls as tools. Therefore, hardened roller bearing balls are generally used, mostly of 100Cr6 (52100) steel with a hardness of approximately 57 to 60 HRC. The shot medium is used in a closed system with return. Ball diameters are usually from 2 to 4 mm, in some cases up to 10 mm.

**Quality Control of the Shot.** Shot peen forming facilities usually control the quality of the shot in the process (Ref 9) to sort out deformed or broken balls. Starting with a sieving process, the shot medium is sorted into different sizes. The shot is fed perpendicularly, continuously, and at constant velocity onto a rotating sieve. A sorting machine checks the roundness of the balls, using the principle of the inclined plane. The shot medium is fed at a defined velocity onto a transverse continuous conveyor belt. Depending on the quality of the balls, they reach the opposite conveyor edge earlier (round balls) or later (balls out of round). An adjustable withdrawal facility classifies the balls according to their quality into separate boxes. Balls of very poor quality stay on the conveyor, drop at the conveyor edge, and fall into the scrap box.

The facility can be designed to be suitable for any shot medium by changing the conveyor inclination, the conveyor speed, the flow, or the positioning of the withdrawal facility.

**Shot Distribution.** The shot impacts on a peened component are statistically distributed, with the shot medium usually spread corresponding to a Gaussian distribution (Fig. 13) (Ref 10).

**Fixtures.** Continuous clamping of the component avoids undesirable inhomogeneities caused by preloading or induced stress. Therefore, the component should not only be fixed at certain points but, if possible, all along its edge. Fixturing on a rubber layer is recommended to allow small movements of the material without inducing additional stresses.

**Fig. 11** Example simulation of shot peen forming for a metal plate. The conditions for this simulation were: explicit calculation with finite element software LS-DYNA3D (Livermore Software Technology Corp.); geometry:  $100 \times 20 \times 2$  mm<sup>3</sup>; material: AlMg<sub>3</sub>; simultaneous double-sided peen forming, upper side: 70 balls, 6.4 mm diam,  $v_B = 17.0$  m/s; lower side: 140 balls, 4.0 mm diam,  $v_B = 6.1$  m/s; stochastically distributed shot impacts; control of kinetic energy of single impacts with calculation of the contact, three-dimensional mesh; fine discretization in the middle of the sample; elastic-plastic material behaviour. ## Process Parameters and Controls

**Influence of Process Parameters on Shot Peen Forming.** The success of shot peen forming of sheet metal components depends on a large number of parameters. To a large extent, they can be determined and used effectively in order to achieve a specific effect, but partly they are determined by the facility itself or the process and cannot be influenced by the operator. Figure 14 gives an overview of all of the process parameters for shot peen forming.

It is important to keep in mind that most of the parameters described previously have a direct or indirect influence on each other. A mass flow increase, for instance, leads to a reduction of the shot velocity with constant peening pressure. The shot velocity and the shot distribution depend highly on the nozzle geometry. Therefore, only the use of different inner diameters of the nozzle leads to greatly different shot intensities and thus different forming results, while all other parameters are unchanged.

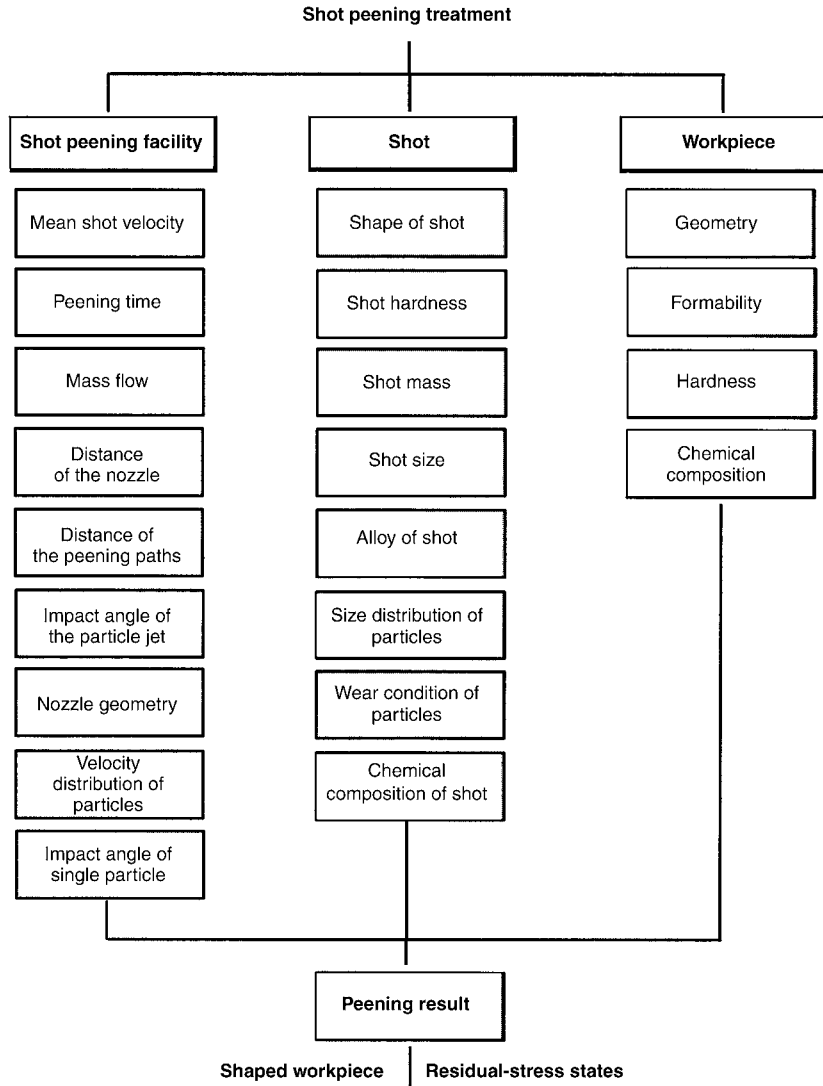

The most important process parameters in shot peen forming are the shot velocity and the degree of coverage.

**Shot Velocity.** The shot velocity has to be squared when calculating the kinetic energy during shot peen forming. The kinetic energy ( $E_{kin}$ ) of a single impact ( $i$ ) is:

$$E_{kin} = \frac{1}{2} \dot{m} \cdot t \cdot \bar{v}^2 = \sum_i \frac{1}{2} m_i \cdot v_i^2$$

Figure 15 is a schematic overview describing the influence of the shot velocity and other material and the process parameters on the residual stresses induced in the cross section (Ref 11).

**Degree of Coverage.** Coverage describes the surface covered by peening impacts compared to

**Fig. 14** Variables influencing peen forming

the total surface of the component. It can also be interpreted as the probability of at least one peening impact on an infinitely small surface element of the component. This interpretation is used to formulate the relation between the shot distribution on the component and the coverage as:

$$A^* = 1 - \exp\left(-\frac{m_A}{m_B} A_{id}\right)$$

where  $id$  is impact diameter. To calculate the degree of coverage ( $A^*$ ), it is necessary to know the shot medium quantity per surface area ( $m_A$ ), the mass of a single ball ( $m_B$ ), and the surface of a single peening impact ( $A_{id}$ ). The shot medium quantity per surface is simplified to:

$$m_A = \frac{1}{z} \cdot \frac{1}{v_n} \cdot \frac{dm}{dt}$$

when the shot spread of the peening path is  $s > 2\sigma$  of the shot distribution.  $z$  is the distance between

**Fig. 15** Effect of alloy and process parameters on the generation of residual-stress states.  $v$ , shot velocity;  $p$ , peening pressure;  $t$ , peening time;  $d$ , ball diameter;  $HV_s$ , ball hardness;  $HV_w$ , workpiece hardness. Source: Ref 11

the peening paths ( $v_n$  is nozzle velocity;  $dm/dt$  is mass flow).

**Material Anisotropy.** Sheet materials with a texture may exhibit anisotropic deformation behavior during peen forming. When being peened, such materials tend to develop larger curvatures transverse to the rolling direction or texture orientation than in the longitudinal direction.

**Workpiece Geometry.** Many components, especially integrated components with a complex geometry and reinforcements, such as stringer and ribs, have different geometrical moments of inertia related to direction. The material flow occurs preferably in the direction of the smallest geometrical moment of inertia, because the lowest forces and moments are needed for material bending.

**Peening Tracks.** The curvature of a component can also be influenced by selecting or determining the peening tracks (Ref 12). For instance, a pressure peening facility can be used to pass over the entire component in one peening process, thus ensuring 100% coverage (Fig. 16a). This leads to a "wrap-up" of the workpiece from one side by generating a curvature perpendicular to the direction of the peening path or track. The stiffening of the sheet metal produced in this way makes it difficult to form a curvature parallel to the direction of the peening path.

The same degree of coverage can be achieved by several peening processes with partial coverage as well, with increasing distance between the peening paths, for example, while all other parameters are unchanged (Fig. 16b). Curvatures after the first peening are not very pronounced, so that bending parallel to the peening path direction is less obstructed.

**Process Controls.** Initially, shot peen forming was performed using a trial-and-error method. Technological progress in facilities and measuring techniques now yield better forming reproducibility. All parameters have to be controlled, especially the positioning, the mass flow, and the peening pressure or the speed. Recent developments deal with on-line measuring of the shot velocity, one of the most important peening parameters. The principle of this measuring method is the scanning of the values by a sensor (Ref 13).

Modern shot peening facilities contain process control equipment, enabling the measurement of the shape of the component by contact scanning or by noncontact optic methods.

**Process automation** of the entire forming process is difficult due to the tolerances in terms of residual stresses, material characteristics,

geometries, and so on, which can have a greater or lesser important influence on the forming behavior. Moreover, operational problems may occur during the process without being registered at once.

Modern process automation follows the principle of adaptive control (Ref 12, 14). With this method, the final degree of coverage required for the desired curvature is achieved in several steps. After each step, the curvature is measured, and the result is used to calculate the forming parameters for the next peening step. Thus, this method allows automatic on-line registering and documentation of all the main process parameters as well as the measurement and subsequent generation of the parameters for the next peening step.

**Peen Forming with Prestresses.** When peen forming is performed together with prestressing of the component by elastic bending or via a method analogous to stretch drawing, it is possible to reduce the flow resistance of the component considerably. Larger deformations, and thus higher curvatures, can thus be developed to strengthen or, in some cases, prevent specific curvatures in a certain direction.

Because the desired curvature of the component is achieved earlier while the peening intensity remains the same, prestressing can increase the effectiveness and thus the profitability of the shot peening process. This is especially valid for simple shapes for which simple prestressing facilities can be used (Fig. 17).

## Materials

In principle, all materials having an elastic-plastic material behavior are suitable for shot peen forming. The process is mainly used to produce large and thin components, as they are used in the aircraft and aerospace industries. Following the need to reduce weight, these are predominantly light metals, above all aluminum alloys. For single-sided concave shot peen forming, the kinetic energy of the balls necessary for plastic deformation on the bottom side of the component has to be high enough, depending on the sheet metal thickness. That is why the sheet

metal thickness suitable for peen forming is from 1 to approximately 8 mm, depending on the specific material. Steel sheet materials can also be used but only with small thickness due to their higher strength.

In general, it has to be considered that the difference between the tool and the workpiece hardness should be high enough to allow high transformation of kinetic energy into deformation energy.

## Specifications

Figure 18 shows some examples of simple and more complicated structural components produced with shot peen forming, demonstrating the wide applicability of this process. It is possible to generate geometries curved in one or more dimensions, according to Ref 15.

**Curvatures and Accuracy.** Due to the large number of different applications, it is impossible to indicate reliable figures. The curvatures that can be achieved as well as the accuracy of the shape depend on the material, the component geometry, and the sheet metal thickness. In general, single-sided convex shot peen forming can be used to obtain radii of curvature of only a few hundred millimeters. On the other hand, there is virtually no limit for the maximum radius of curvatures; that is, almost flat sheet with very large radii of 30 m and even more can be produced. Tolerances for convex shot peen forming are in tenths of millimeters. Single-sided concave shot peen forming can be used to produce curvatures with radii of approximately 1000 to 3000 mm, depending on the component geometry and the material used. Due to higher kinetic energy generated and process variations occurring during concave shot peen forming, compared to convex forming, the accuracy of concave forming with large panels is usually between 1 and 3 mm.

**Surface Characteristics.** Every shot peening process changes the topography of the peened surface. The surface roughness is increased when the shot velocity is increased or the ball diameter reduced. The harder the shot compared to the workpiece, the lesser the plastic deformation of

Fig. 16 Influence of the nozzle guidance. Source: Ref 12

Fig. 17 Examples of clamping fixtures for pretensioning. Source: Ref 12

the shot and thus the higher the energy transfer into the workpiece. According to Ref 16, the shot hardness should be at least twice the workpiece hardness to avoid plastic deformation.

When peened, the surface of a component is characterized by circular impressions that are

statistically distributed and can thus be overlapping. To give an example, some surface topographies are illustrated in Fig. 19, 14 times magnified, for two ball diameters (6.4 and 4.0 mm diameter) at different shot velocities.

Fig. 18 Possible shapes and contours producible by shot peen forming. Source: Ref 15

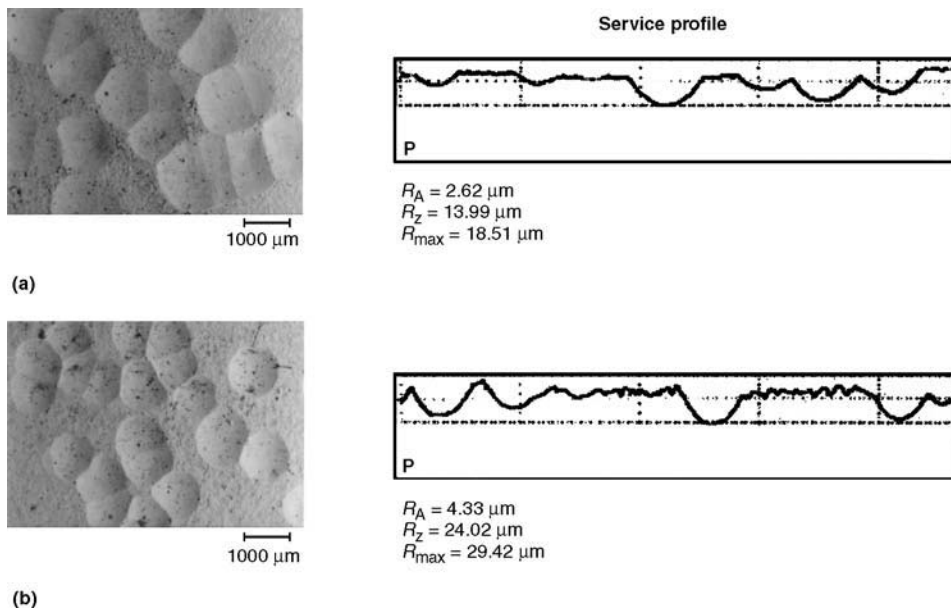

Fig. 19 Surface topography of shot peened workpieces with (a) 6.4 mm ball diameter and 15 m/s ball velocity, and (b) 4.0 mm ball diameter and 12.8 m/s ball velocity.  $R_A$ , roughness average;  $R_z$ , ten-point height (roughness average);  $R_{max}$ , maximum peak-to-valley roughness height

Ball impressions become larger and deeper with increasing velocity, whereas larger ball diameters make local deformation more difficult. As a consequence, larger ball diameters generally lead to lower surface roughness.

**Material Removal.** Because the shot used for shot peen forming has smooth, round surfaces, there is almost no material removal from the workpiece.

**Work Hardening.** The impacts of the balls onto the workpiece surface cause work hardening or partial even smoothening. Which of the two effects occurs depends mainly on the material hardness. Smooth materials will harden; hard materials can become smoother (Ref 4). This behavior can be explained by an increase of the dislocation density within smooth materials and the rearrangement of dislocations within hard materials.

## Typical Applications

**Aerospace Industry.** In the aircraft and aerospace industries, shot peen forming has been successfully used for many years to form numerically controlled milled components, such as airplane wings, stringer-strengthened fuselages (Alpha Jet, Airbus), or structural segments of spacecraft (Ref 12, 17, 18). The first industrial application of the shot peen forming process was as early as 1952 when Lockheed applied the method to form stringer-stiffened wing panels for the Super Constellation (Ref 19).

Table 1 gives an overview of shot peen forming applications in the aircraft and aero-

space industries (Ref 20). Some typical components used in the aircraft and aerospace industries are described in Ref 21 to 24. Examples are shown in Fig. 20 and 21.

**Double-sided simultaneous shot peen forming (Ref 25)** is an optimized process that enables three-dimensional components to be formed much more efficiently. On the one hand, process productivity is enhanced by conducting shot peening on both sides at the same time; on the other hand, this technique can be used to achieve smaller radii and to produce superposing curvatures. With double-sided simultaneous shot peen forming, the plastic deformation of the entire cross section can be guaranteed despite considerably lower shot intensity.

All parameters used in double-sided shot peening have to be adapted for each side due to the influence they have on each other. Therefore, pretests run for the peening of each side separately cannot be used to determine the optimal parameters for each side by itself. Figure 22 shows the configuration of a facility designed for double-sided simultaneous peen forming.

**Straightening of Stringer Reinforcements (Ref 21).** Modern aircraft contain fuselages with stringer reinforcements fixed by laser

welding. The heat generated during the welding of the stringers onto the fuselage may lead to an unintended deformation of the component. With shot peen forming, it is possible to straighten the fuselages and restore the original shape. This is done by specifically peening local areas of the stringer reinforcements (Fig. 23).

## ACKNOWLEDGMENTS

Parts of the presented research results were supported by the Deutsche Forschungsgemeinschaft DFG in Bonn, Germany. The authors also thank the Kugelstrahlzentrum Aachen GmbH for their cooperation.

# Age Forming

Jacob A. Kallivayalil, Alcoa Technical Center

AGE FORMING is a shaping process for heat treatable aluminum alloys that is gaining popularity. In this process, parts are given an aging treatment while simultaneously being subjected to mechanical shaping loads. It is used mainly for large parts that have to be imparted a curvature. The part shape is obtained due to the creep that occurs at the aging temperatures (120 to 190 °C, or 250 to 375 °F). Because creep is the phenomenon responsible for achieving the part shape, age forming is sometimes referred to as creep forming. The most common application for age forming is the shaping of upper wing skins in the aerospace industry. Recent investigations (Ref 1) have looked into the possibility of using age forming for damage-tolerant lower wing applications. Age forming is also used for shaping extrusions for the transportation industry. An example of extrusions shaped by age forming is shown in Fig. 1. This method offers several advantages over the conventional process path where the material is typically solution heat treated and then cold formed by shot peening or roll forming.

During conventional cold forming, plastic deformation is imparted to the surface layers of the part such that after the forming loads are released, the part springs back to the desired shape. This results in nonuniform microstructure, because the surface layer has a significantly larger plastic deformation than the bulk. During age forming, the forming loads are often lower than the yield stress of the material, and the part shape is obtained due to the

low-temperature creep that occurs during the aging process; hence, there is less nonuniformity in the microstructure. Compared to cold-formed parts, age-formed parts have lower residual stresses and consequently better stress corrosion resistance.

## Technical Issues

Creep in aluminum alloys at slightly elevated temperatures was first investigated as part of the effort to develop alloys for supersonic flight (Ref 2, 3), where wing tip heating is a concern. Most investigations (Ref 4–6) of creep in precipitate-strengthened materials have, however, dealt with fairly stable precipitate microstructures. The situation where the precipitate microstructure is unstable has not been investigated thoroughly.

Rösler and Arzt (Ref 7–9) have investigated the interaction between precipitation and creep.

They suggested that the creep resistance may be due to an attractive interaction between dislocation segments and dispersed particles. They have also suggested relations for the dependence of the creep rate on the particle size and particle spacing for dispersion-hardened material. According to them, for a fixed volume fraction of particles, the creep resistance increases with increasing particle size up to an optimal size, beyond which the creep resistance falls. The optimal size is determined as a trade-off between the probability of detachment of dislocation segments from a precipitate and the actual athermal stress required for detachment. This optimal precipitate size is not the same as the precipitate size where the peak aged strength is observed. The peak aged strength is determined by the precipitate size where the precipitate cutting and bypassing strengths are equal during dislocation glide.

The variation in age formability with aging may be observed in Fig. 2. Here, the stress relaxation curves for alloy 7055 given four

Fig. 1 Age-formed extrusion profiles

Fig. 2 Impact of initial state on relaxation behavior

different initial treatments prior to a stress relaxation test are presented. The stress drop shown in Fig. 2 is the difference between the initial applied stress and the stress measured at any instant. This stress drop is proportional to the retained plastic strain and hence the age formability of the specimen. The creep resistance increases up to 6 h of aging at 120 °C (250 °F) but subsequently decreases for an initial treatment of 14 h at 120 °C (250 °F). This observation is consistent with the mechanism suggested by Rösler and Arzt.

In addition to the effect of the evolving precipitate microstructure on creep, one must also consider what effect the applied stress has on the aging process. The impact of applied stress on the aging process has been addressed in a series of investigations on aluminum-copper alloys by Zhu and Starke (Ref 10–12). They addressed the issues of stress affecting the aging kinetics and the changes to the precipitate morphology as a result of applied stress. From hardness measurements they concluded that the overall aging kinetics were unaffected by

the applied stress, at least for stress magnitudes normally encountered during the age-forming process. The main effect of applied stress was on the orientation of the platelike precipitates that form in aluminum-copper alloys. These effects of applied stress on the aging process have not been assessed in other alloy systems.

## Prediction of Final Part Shape

The ability to predict the final part shape is crucial for a successful age-forming operation, because parts that are out of tolerance have to be mechanically formed to get the final part shape, voiding many of the advantages of the age-forming process. The general program for predicting final part shape is shown in Fig. 3. The different steps involved in this program are discussed in further detail during the rest of this article. The basic steps involve developing mechanical tests to study creep at low temperatures and low stresses, describing low-temperature creep in terms of a constitutive model, and then using the constitutive model in a process model or finite element analysis to predict final part shape. For simple cross-sectional shapes such as plates, a process model is sufficient to predict the final part shape. For more complicated cross-sectional shapes such as extrusions, finite element analyses that incorporate the appropriate constitutive models have to be employed.

**Testing Methods for Studying Creep.** The strain rates encountered during age forming are in the range of  $10^{-8}$  to  $10^{-4}$  s $^{-1}$ . To study constitutive behavior in this regime, stress relaxation tests or creep tests can be used. During stress relaxation tests, a fixed displacement is applied to the specimen, and the variation in load with time is studied. During creep tests, a fixed load is applied to the specimen, and the variation of strain with time is studied. Both types of tests generate equivalent information.

A typical stress relaxation curve is shown in Fig. 4. During a fixed displacement test, the plastic strain rate can be related to the stress rate through the elastic modulus, according to Eq 1. The elastic modulus,  $E(T)$ , used in determining the plastic strain rate is temperature dependent. The elastic modulus at the testing temperature can be estimated during the unloading part of the stress relaxation test:

$$\epsilon^{\text{Total}} = \epsilon^{\text{Plastic}} + \epsilon^{\text{Elastic}} = \text{constant};$$

$$\frac{d(\epsilon^{\text{Plastic}})}{dt} = \frac{-d(\epsilon^{\text{Elastic}})}{dt} = \frac{-1}{E(T)} \frac{d\sigma}{dt} \quad (\text{Eq 1})$$

The differentiation of stress/strain histories presents numerical difficulties due to the noise that is inherent in experimental data. Hence, the stress/strain history is first fit to an algebraic expression and then differentiated. The fitting of algebraic expressions to the experimental data is

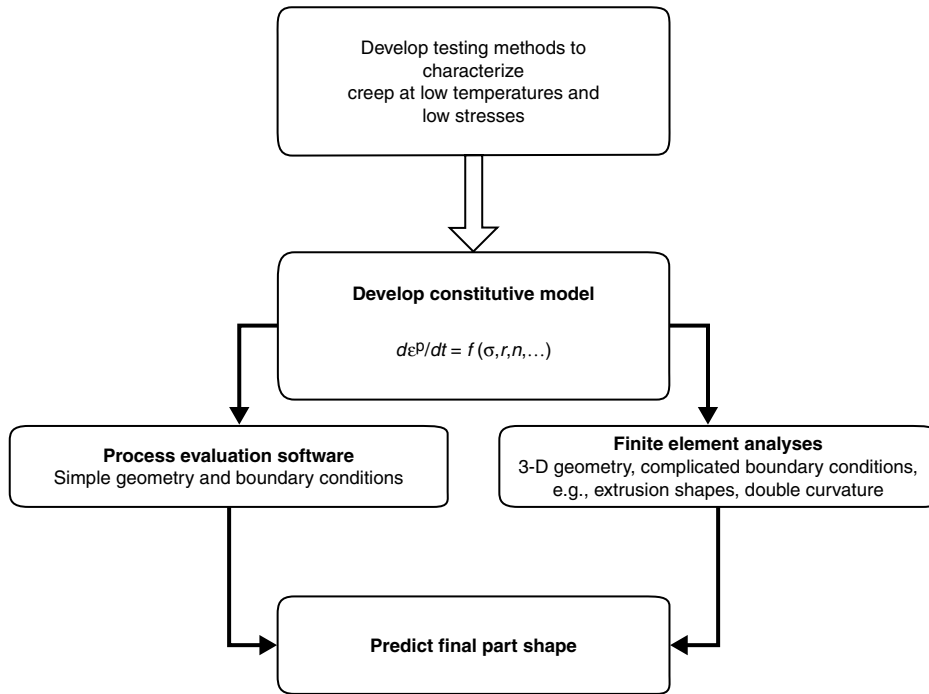

Fig. 3 General program for predicting final part shape during age forming

Fig. 4 Typical stress relaxation curve

an ill-posed problem, and proper regularization techniques (Ref 13) should be employed to obtain meaningful fits. A fit of the load history to a sum of exponential terms is shown in Fig. 4. The sum of exponential terms can be differentiated to obtain the creep rate as a function of stress.

Constitutive Model Development

To develop constitutive equations, simple uniaxial tension or compression tests are performed, because the stress state is easy to determine. The constitutive equation predicts the creep rate as a function of the applied stress ( $\sigma$ ), temperature ( $T$ ), and other parameters representing the microstructure:

$$\frac{de^p}{dt} = f(\sigma, T, r, n, \dots)$$
 (Eq 2)

During aging, the parameters representing the microstructure could be the average radius ( $r$ ) and number density ( $n$ ) of precipitates. These parameters evolve, and hence, one needs evolution equations for them to complete the constitutive equation. In the event that explicit evolution equations for microstructural parameters cannot be determined, approximate phenomenological constitutive relations can be obtained by scaling experimentally determined stress-versus-strain-rate curves. Guidelines for scaling data obtained during creep or stress

relaxation tests have been provided by Povolo and Rubiolo (Ref 14) and also by Fortes and Rosa (Ref 15).

Once a constitutive model has been developed, it can be verified by applying a four-point bend loading and comparing the final measured curvature to the curvature predicted by the constitutive model. The final curvature can be predicted once the constitutive model is determined, using a general process model described later. The oven and loading fixtures used for these tests are shown in Fig. 5 and 6.

Process Model for Age Forming

The necessary pieces of information required for an age-forming process model are shown in Fig. 7. In Fig. 7, the arrows on the top represent inputs that are material constants or thermal and mechanical boundary conditions. The arrows to the left are inputs representing the evolving microstructure. These inputs have to be initialized prior to running the model. The arrows below represent the quantities that the model tries to predict.

Fig. 6 Bending fixture and specimen with extensometer

Fig. 5 Bending-loading fixture in temperature-controlled oven

Fig. 7 General process model for age forming

For extrusion and plate products, an initial residual-stress state may be present as a result of heat treating and stretching. These stresses are superposed on those applied by the loading fixture. The residual stresses may be comparable in magnitude to the applied loads and should not be ignored.

Because the loading fixtures try to impart a curvature, there is a variation in applied stress through the cross section of the part. Thus, depending on the initial yield strength of the part and the curvature imposed, it is possible that the outer regions of the part yield plastically. This will result in a curvature that should not be mistaken for age formability. In order to determine the initial stress state after yielding, it is necessary to know the hardening behavior of the material. Once the initial stresses are known, it is possible to determine the impact of the initial plastic deformation on the final curvature of the part by the moment release method described later.

Different means of load application can be used. Dies are typically used for plate products

and clamps for extrusions. Occasionally, dies that impart double curvatures are used. Depending on how the part is clamped, the differential thermal expansion between the clamping material and the part could introduce additional thermal stresses, which are superposed on the applied stresses. Further, there is a volume change associated with precipitation that can change the stress state. The volume shrinkage can be significant for large parts such as wing skins.

The final shape after elastic springback can be estimated for simple shapes by the moment release method. For circular dies, a formula for estimating the curvature in terms of the constitutive model is presented in Fig. 8. Sallah, Peddieson, and Foroudastan (Ref 16) have suggested ways of dealing with dies that are not circular in shape. The constitutive model allows one to predict the stress,  $\sigma(z, t)$ , at any point in the cross section at any time. From this, the retained radius at any time,  $r(t)$ , can be estimated.

## Conclusion

Age forming is a shaping process that offers significant advantages, but it also presents numerous challenges. It is anticipated that with increasing research activity in the area of creep at intermediate temperatures, age forming will become the method of choice for the shaping of large aluminum parts. The issues addressed in this article will help develop alloys and tempers that are particularly suited for the age-forming process.

# Shearing of Bars and Bar Sections

BARS AND BAR SECTIONS are sheared between the lower and upper blades of a machine in which only the upper blade is movable. As the upper blade is forced down, the work metal is distorted and caused to fracture. There are also shears, such as impact cutoff machines, that use a horizontal knife movement to shear the bar sections. Figure 1 shows the appearance of a sheared round bar. The burnished area, or depth of shear action by the blade, is usually one-fifth to one-fourth the diameter of the bar. In visual examination of a sheared edge, the burnished portion appears smooth, while the fractured portion is comparatively rough. Shearing, in some cases, may be associated with crude cuts and distorted parts—generally when parts are cut only on inexpensive universal-type shears. However, with proper tooling and machines, nondistorted, burr-free cuts are possible.

## Applicability

In structural and bar shearing, the cost of cutoff is a small percentage of the overall cost. Materials handling and setup, along with die changes, are most important from a cost standpoint.

The cost of cutting off a bar of steel (Fig. 2), regardless of how it is cut, is determined by the following formula:

$$C = \frac{S+T}{N} + R$$

where C is total cost per part, S is setup cost, T is tool cost, N is number of pieces to be cut, and R is running cost (feed, cut, discharge).

In general, any metal that can be machined can be sheared, but power requirements increase as the strength of the work metal increases. Further, blade design is more critical and blade life

decreases as the strength of the work metal increases. Equipment is available for shearing round, hexagonal, or octagonal bars up to 152 mm (6 in.) in diameter or thickness, rectangular bar and billets up to 75 by 305 mm (3 by 12 in.) in cross section, and angles up to 203 by 203 by 38 mm (8 by 8 by 1½ in.).

Straight blades can be used to shear bars and bar sections, although a considerable amount of distortion occurs, as shown in Fig. 1. In addition, the concentration of shock on the blades is high when shearing with straight blades (particularly when shearing round bars). Preferred practice is to use blades that conform to the shape of the work metal, as discussed in the section "Blade Design and Production Practice" in this article. Angles are usually sheared in a special machine or in a special setup with conforming blades.

Because of the conditions illustrated in Fig. 1, the edges sheared with straight blades are not as high quality as edges that are sawed or otherwise machined. However, when blades are sharp and accurately adjusted, sheared edges that are acceptable for a wide range of applications can be obtained. The quality of sheared edges usually increases as thickness of the work metal decreases.

**Accuracy of Cut.** Workpieces properly supported on both sides of the shear blades by a roller conveyor table and placed squarely against a gage stop securely bolted to the exit side of the machine can ordinarily be cut to lengths accurate to +3.2, -0 mm (+1/8, -0 in.) on shears that can cut bars up to 102 mm (4 in.) in diameter. When larger shears are used, the breakaway of the metal can cause a variation of ±4.8 mm (3/16 in.). Fairly consistent accuracy in the shearing of slugs can be obtained by careful adjustment of the gage setting, especially if the slugs are produced on a weight-per-piece basis. Supporting the free end of the material on a spring-supported table will minimize bending during the shearing operation, thus providing better control over the length of cut.

**Selection of Cutoff Method.** The method of cutting off bars can be determined by the edge condition required for subsequent operations. Sawing usually produces a uniform cut edge with little or no damage to the microstructure in the immediate area. Gas cutting produces an edge that resembles a sawed edge in smoothness and squareness. However, the cut edge of some steels becomes hardened during gas cutting, thus making subsequent machining difficult.

Fig. 1 Effects of shearing a round bar with a straight blade

Fig. 2 Typical shapes that can be sheared

A sheared edge is usually easy to machine but can make the fit-up of parts of a weldment more difficult and can increase warpage because of wider gaps.

**Power Requirements.** The net horsepower (hp) required for shearing can be estimated from the following formula:

$$hp = A \cdot V \cdot S / 33,000 \quad (\text{Eq 1})$$

where  $A$  is the cross-sectional area of the workpiece (in square inches),  $V$  is the speed of the shear blade (in feet per minute), and  $S$  is the shear strength of the work metal (in pounds per square inch). The 33,000 is foot-pounds per minute per horsepower. For metric use, the power in English units (hp) should be multiplied by 0.746 to obtain kilowatts. It may be necessary to increase the calculated value as much as 25% to compensate for machine inefficiency.

Although Eq 1 is used for estimating, it is of limited value because it does not consider the ductility of the metal. The formula is based on shearing low-carbon steel. Copper, for example, is more ductile than steel; therefore, the distance of blade penetration before fracture in copper will be greater than that in steel. Conversely, when shearing metals that are less ductile than low-carbon steel, the distance of blade penetration before breakaway will be less. Power requirements are also affected by the ductility of the work metal.

**Cutting Speed.** The speed at which material is sheared without adverse effect can range from almost zero to 21 or 24 m (70 or 80 ft) per min. However, as speed increases above 6.1 or 7.6 m (20 to 25 ft) per min, problems are encountered in holding the workpiece securely at the blade without the far end whipping, especially with material 6.4 mm ( $1/4$  in.) thick or more. When bars harder than 30 HRC are cut at speeds of 12 to 15 m (40 to 50 ft) per min or higher, chipping of the blade is common (see the section "Example 1: Reduction in Speed for Prolonged Blade Life" in this article).

**Alternative Cutoff Methods.** Sawing with a hacksaw, a radial saw, or a band saw is the most widely used cutting method, but it is also the most costly. Sawing must be used for cutting certain shapes and sizes for economic or quality reasons, for example, cutting of thick-wall round tubing. However, the average plant does not have to saw everything, and consequently, vast

savings can be realized on parts that can be sheared.

Table 1 is a chart compiling the times required to cut various types of bars using a hacksaw, a band saw, a high-speed steel band saw, and a hydraulic shear. The cost of deburring the sawed ends is not included, but in most cases, this operation is required after shearing. Another cost not included is the blade cost per cut, which is much higher for sawing than for shearing.

Abrasive and friction cutting offer the advantages of cutting various shapes without changeover costs, production of flat nondistorted ends, and rapid cutting. Their main drawbacks are the high blade cost per cut and the cost of deburring both ends of the cut part. A very sharp razor edge is usually produced and is dangerous if not completely removed.

## Punching and Shear Machines

Punching and shearing machines are deep-throat C-frame machines for the punching, shearing, notching, or coping of plates, bars, and structural sections. The production shearing of bars and bar sections is usually done in machines with a throat opening designed for large, bulky workpieces. High-quality cut slugs or blanks of precise length from round, square, or specially shaped bars or coils can also be produced with impact cutoff machines (see the section "Impact Cutoff Machines" in this article).

Iron workers (Fig. 3) are heavy-duty shears used primarily for preparing structural shapes such as bars, angles, and T-bars. Like the shears used for plate and flat sheet, iron workers leave a square butt edge that may require further preparation for heavier sections. These machines include alligator and guillotine shears and multipurpose (combination) machines. The multipurpose machines feature interchangeable punches and dies for shearing, punching, and coping. Squaring shears, normally used for sheet and plate, can also be used for cutting bar stock to length.

Punch presses and press brakes can be provided with appropriate tooling for cutting operations. Shoes, into which punches, dies, and shear blades can readily be inserted, are mounted on the bed and ram. The shoes either rest on the bed or are overhung; the overhanging type is

designed so that structural shapes can be punched in both web and flange. The plain type of shoe is primarily used for plate work; however, plates can be worked with the overhanging shoes. Both types of die blocks are fitted with die sockets that hold dies of different inside diameters. The punch holder is adjustable to suit the location of the dies. Table 2 lists the capacities for punching and shearing with this type of machine.

Hydraulically powered shears help fill the need for fast-cycling shear cutting of structural and bar-shaped parts with little or no distortion or burring. Hydraulic power can apply high forces throughout a relatively long stroke, due to the rake angle of the shear blade. Hydraulic power is noted for its maintenance-free performance, shock-free operation, and the ability to operate more than one machine from a single power source. The stroke of the ram can also be controlled for quicker cycle times. For example, if the cycle time required for cutting 150 by 150 by 13 mm (6 by 6 by  $1/2$  in.) angle iron is 7 s, the cutting of 50 by 50 by 6 mm (2 by 2 by  $1/4$  in.) angle iron can be done with a cycle time of only 3 s when the stroke length is reduced by more than half. Several different stroke lengths may be

available on hydraulic machines for selection by the operator.

### Alligator Shears

In alligator shears (also known as pivot or nutcracker shears), the lower blade is stationary, and the upper blade, held securely in an arm, moves in an arc around a fulcrum pin (Fig. 4). The shearing action is similar to that of a pair of scissors. A crankshaft transmits power to the shearing arm, and the leverage applied produces the force for shearing. Maximum shearing force is obtained closest to the fulcrum, and the mechanical advantage decreases as the distance between the point of shearing and the fulcrum increases. Therefore, with the maximum opening (largest rake angle), capacity is maximum for any shear. As the blade begins downward travel and rotation about its fulcrum, the cross-sectional area engaged by the blade is increased; therefore, more energy is expended, and the upper blade is slowed down until the breakaway point is reached. At this point, the mechanical forces have overcome the resistance of the metal, and the remainder of the cross-sectional area breaks off.

The capacity of an alligator shear is designated as the maximum cross-sectional area of flat plate or round bar that can be sheared, based on work metal having a tensile strength of 275 MPa (40 ksi). An alligator shear can be used not only for bars and bar sections but also for plate, sheet, and strip within the limitations of the blade length of the machine. Alligator shears are extensively used for preparing scrap because the single pivot point allows the blades to open wide enough to accept bulky objects. For example, on a machine with 300 mm (12 in.) long blades, the opening between upper and lower shear blades is approximately 135 mm (5 1/4 in.); on a machine with 915 mm (36 in.) long blades, the opening can be as great as 280 mm (11 in.).

The two types of shearing arms used on alligator shears are low-knife and high-knife (Fig. 4). In the low-knife type, the cutting edge of the lower blade is in line with the center of its fulcrum pin; in high-knife shear, the cutting edge of the lower blade is on a plane above the centerline of the fulcrum pin. In general, the low-knife shear is preferred for cutting bars and bar

sections. The high-knife shear is preferred for cutting flat stock and for use in scrap yards. A high-knife shear, by making successive cuts, can shear flat stock that is wider than the length of the shear blades. An alligator shear is further classified as either right-hand or left-hand (each is shown in Fig. 4), depending on the side from which it is fed.

The weight of alligator shears ranges from approximately 1,100 to 19,500 kg (2,500 to 43,000 lb). The lighter shears can be made portable on wheels, on a sled-type skid, or on blocks. The heavier machines must be anchored in concrete.

The speed of alligator shears ranges from approximately 50 strokes per minute for the smallest power-driven machine to approximately 18 strokes per minute for the largest heavy-duty shear. Except for small hand-operated types, alligator shears are usually mechanically driven; a flywheel provides uniform, sustained power during cutting.

The number of strokes per minute can be reduced by changing either the motor speed or the diameter of the flywheel pulley. An increase in the number of strokes may affect the stored energy of the flywheel and reduce the shearing capacity. On continuously cutting shears, greater speed will reduce workpiece-positioning time for the operator and therefore may reduce output rather than increase it. On single-stroke machines, cutting time is minimal compared to the time required for accurate positioning of the stock.

### Guillotine Shears

Guillotine shears are designed for cutting bars and bar sections to desired lengths from mill stock. They are extensively used throughout the fabricating industry. Guillotine shears for bars and angles are available in capacities to 2700 kN (300 tonf). Either intermittent or continuous operation is possible. Guillotine shears can be equipped with simple straight blades (Fig. 5) or with two or more short blades having specific shapes.

Two general types are available: open end and closed end. An open-end shear has a C-frame construction (Fig. 5) with one end open and unsupported. Open-end shears are either single end, for one operator, or double end, for two operators. On double-end machines, both ends can be right-hand or left-hand, or one end can be right-hand and the other end left-hand, depending on the type of shearing to be done.

An open-end shear has the advantage of giving the operator a clear view of the blades. However, because one end is open, a heavier frame and more floor space are required than for a closed-end shear of equal capacity. A closed-end guillotine shear, on the other hand, is basically the same as the one shown in (Fig. 5) except that it has frame supports on both sides.

Guillotine shears are actuated mechanically, hydraulically, or pneumatically. Hydraulic and pneumatic machines are lighter in weight for a specific shearing power, are more economical,

Fig. 4 Low-knife and high-knife alligator shears. See text for discussion.

Table 2 Maximum workpiece dimensions that can be accommodated in vertical open-cap punching and shearing machines of various tonnage ratings

and operate with less vibration than mechanical shears. Therefore, hydraulic or pneumatic machines up to 90 kN (10 tonf) capacity are completely portable, and units of 1800 to 2700 kN (200 to 300 tonf) capacity are semiportable (need not be solidly mounted in concrete).

### Combination Machines

Combination machines are multipurpose machines used primarily in metal-fabricating shops where there is a constant need for shearing small quantities (often two or three pieces) of a variety of shapes and sizes from bars or bar sections. Some combination machines can also be used for punching, slotting, and notching.

Many combination machines incorporate several devices within the frame for performing different operations; therefore, a new setup is not required for each. A holder for an interchangeable punch and die is located in an area with a deep throat. This facilitates the punching of holes, slots, or notches in plates and bars, and in webs or legs of structural members.

A slide moving at 45° from vertical carries a blade for shearing angles. The support bed is on a swivel so that the ends of the angle section can be varied as desired from 45 to 90°. In two strokes of the machine, angles can be sheared to produce miter joints for subsequent welding (see the section "Shearing of Angles" in this article).

Combination machines can be used for cutting square and rectangular notches in the leg of an angle. These machines can be set up to cut a 90° V-shaped notch in angles that subsequently will be bent into frames. Other shapes, such as beams and channels, can be notched in a similar manner if the machine can accommodate the vertical height between the upper and lower legs of the workpiece. Provision is also made for shearing bars with guillotine-type blades or special blades (see the section "Conforming Blades" in this article).

Combination machines are available in capacities ranging from 110 to 890 kN (12 to 100 tonf). The 110 kN (12 tonf) machine can punch a 14 mm ( $\frac{9}{16}$  in.) diameter hole through a 6.5 mm ( $\frac{1}{4}$  in.) thick section and can shear 75 by

75 by 6.4 mm (3 by 3 by  $\frac{1}{4}$  in.) angle sections, 22 mm ( $\frac{7}{8}$  in.) diameter rounds, 19 mm ( $\frac{3}{4}$  in.) squares, and 100 by 6.5 mm (4 by  $\frac{1}{4}$  in.) flats. The 890 kN (100 tonf) machine can shear 150 by 150 by 16 mm (6 by 6 by  $\frac{5}{8}$  in.) rounds, 50 mm (2 in.) squares, and 200 by 19 mm (8 by  $\frac{3}{4}$  in.) flats.

### Shear Blades

Shock-resistant tool steels such as S2 or S5 are most commonly used as blade materials for cold shearing, although L6 has also been successfully used for some applications. Some plants use shear blades made from carbon or alloy steel with hardfaced shearing edges.

The hardness of tool steel blades usually ranges from 45 to 55 HRC (sometimes as high as 58 HRC). The upper end of this range can be used when work metal thickness does not exceed 13 mm ( $\frac{1}{2}$  in.). As work metal thickness increases, the hardness of the blade should be decreased to the lower end of this range, but not below 45 HRC unless experience with previous applications warrants it. The practice in most plants is to start with blades near the lower end of the range, increasing their hardness only after experience proves it safe. Excessive blade wear is usually preferable to blade breakage.

**Blade Material for Hot Shearing.** Blades for the hot shearing of bar stock are usually made of H11, H12, or H13 hot work tool steel. Tool steel for blades can also be made of compositions manufactured by powder metallurgy processes. There are no data to prove the superiority of one of these steels over the others. Grades H21 and H25 are sometimes used, but they are more costly and are recommended only when H11 has been tried and found to be inadequate.

The hardness of blades for hot shearing varies considerably with the thickness and temperature of the metal to be sheared and with the type and condition of the shearing equipment. However, hardness is usually maintained at 38 to 48 HRC.

For high-alloy metals to be sheared at high temperatures, higher-alloy blades may be needed. High-temperature engine-valve alloys have been sheared with T1 high-speed steel blades. Hardfaced blades are satisfactory for hot

shearing and are used exclusively in some plants. The material for the blade body is usually 1030 or 1045 steel.

**Blade Profile.** The cross section of an alligator shear blade for cutting bars and shapes is normally rectangular. Light-duty blades are approximately 32 mm ( $1\frac{1}{4}$  in.) wide by 100 mm (4 in.) deep by 300 mm (12 in.) long. Blades for machines of approximately maximum size are commonly about 50 by 125 by 915 mm (2 by 5 by 36 in.). For mounting, blades are provided with countersunk holes, as shown in Fig. 6, that allow bolt heads to be sunk sufficiently to prevent interference between blades.

Blade clearance for shearing bars and bar sections ranges from 0.13 to 0.38 mm (0.005 to 0.015 in.). The smaller clearance is used for shearing clean work metal; the larger clearance is preferred for shearing scaly products to prevent scale or other foreign material from lodging between blades and scoring the surfaces.

Blades for alligator shears are available with grooves across the width to prevent forward movement of the work metal when the upper blade descends, so that more of the cutting length of the blade can be used. Most blades have four cutting edges that are identically ground (Fig. 6); therefore, by inverting the blade and reversing its direction, all four cutting edges can be used before the blade is returned for sharpening. Resharpening any of the four edges requires grinding of one or both faces of an edge. Consequently, a blade that shows severe damage, such as breakout of a section, must be ground to a new, clean, and sharp edge. To avoid such major regrinding, blades should be kept free from large nicks and mushrooming.

Most blades are ground to a slight negative rake, as shown in Fig. 6. The intent is to cause the work metal to begin to flow from a slight bending action before actual shearing takes place. Blades provided with a negative rake of 5 to 10° are often less susceptible to chipping at the cutting edge than those ground with a 90° edge (zero rake).

**Shear Blade Life.** Service data on shear blade life are scarce because maintenance programs in most high-production mills call for removal of blades and redressing during scheduled shutdowns, regardless of the condition of the blades at the time. Blade life in number of cuts before regrinding has been variously reported at 5000 to more than 2 million. Even when an attempt is made to make blade material and cutting conditions as nearly identical as possible, variations in blade life of 100% or more have been reported.

Blade life depends to a great extent on the composition and hardness of the work metal (see the article "Selection of Materials for Shearing, Blanking, and Piercing Tools" in this Volume). The angle of the cutting edge often affects blade life, and in some cases, shearing speed has a marked effect on blade life. For example, harder work metal usually requires a lower shearing speed in order to avoid blade chipping and premature dulling. When work metal hardness is

Fig. 5 Open-end guillotine shear

Fig. 6 Straight shear blade ground with negative rake on all four cutting edges

30 HRC or higher, speeds greater than 15 m (50 ft) per minute are not recommended, and much slower speeds may be required for acceptable blade life. The following example demonstrates the effects of blade angle and speed on blade life.

**Example 1: Reduction in Speed for Prolonged Blade Life.** Blades had to be replaced every 2 to 3 weeks (200 to 500 cuts) because of chipping when shearing 1085 flat spring steel with hardness ranging from 30 to 34 HRC. The stock was 3.2 and 4.8 mm ( $\frac{1}{8}$  and  $\frac{3}{16}$  in.) thick and 50 mm (2 in.) wide, and it was sheared to lengths of 1.2 and 1.5 m (4 and 5 ft) at a blade speed of 21 m (70 ft) per minute in a punch press. In addition, regrinding was required during this period. When the procedure was changed to shearing at 3 m (10 ft) per minute in a C-frame shear, blade life was increased to an average of 10,000 cuts before regrinding was required, and chipping was eliminated. Blades for both the punch press and the shear were made from S1 tool steel and ranged in hardness from 54 to 56 HRC.

**Cost.** Because of the relatively small amount of machining needed to make a shear blade, compared with the machining needed to make an

intricate impression in a die block or a forming die, the cost of the material is an important part of the total cost of a blade. A blade made from S2 tool steel costs 1.8 times as much as one made from W2 tool steel, and 0.7 times as much as one made from D2 tool steel.

## Blade Design and Production Practice

The straight-edge blades (Fig. 6) described in the preceding section can shear almost any bar or shape that is within the capacity of the machine. However, unacceptable distortion may result in some shapes of workpieces when they are sheared with blades that are not designed for cutting specific shapes.

**Conforming Blades.** One method of minimizing distortion in sheared bars employs two hardened blades mounted face-to-face, with identical holes through each blade. The holes should conform to the shape of the work metal and should be large enough to allow easy passage through the blades (Fig. 7a). One blade is movable vertically and one is stationary. Relatively little movement of the machine is required when blades of this type are used. In addition, because the blades completely encircle the work metal, holddowns are not needed. However, these blades are usually limited for use on specially built or combination machines.

The shearing of round and square bars is more frequently done with the open-type blades illustrated in Fig. 7(b). Each blade is contoured to accommodate one-half the cross section of the work metal. The upper blade moves in a vertical direction, while the lower blade remains stationary. When using this technique, some type of holddown is needed. Because of the stiffness of the work metal, the holddown for bars should permit slight movement of the work metal in the axial direction to avoid double shearing. The holddown can be a simple set screw (to permit adjustment) in a bracket or can be a more elaborate unit, such as a handwheel assembly using an Acme thread.

For shearing square bars with any type of blade, the work metal should be placed so that

the movement of the blade is across the diagonal of the square. With this technique, the shearing force is applied to four sides instead of two, resulting in a smoother sheared surface. Shearing across the diagonal provides support on two sides of the square shape, which minimizes distortion, and permits more than one size of bar stock to be sheared in a given hole.

Best practice for shearing round bars is to use blades with holes for each size of stock to be cut. Blade holes appreciably larger than the stock size cause excessive distortion of the workpiece.

**Shearing of angles** is done either in a combination machine or by double cutting. In a combination machine—the more common method—two blades such as those shown in Fig. 8(a) are used. One blade, usually the one that is stationary, is L-shaped and is positioned as shown. The movable blade is square or rectangular and is mounted with its two cutting edges parallel to those of the stationary blade. Figure 8(a) also shows that the space between the blades in the loading position is the same shape as the workpiece.

The movable blade travels at 45° toward the stationary blade, and both blades contact the work metal uniformly. Shearing by this technique is essentially a blanking cut, and distortion of the workpiece is minimal. One disadvantage of the method is that all cutting occurs at once, resulting in a high shear load. This condition is not important when small angle sections are cut; however, for work metal larger than 100 by 100 by 13 mm (4 by 4 by  $\frac{1}{2}$  in.), the movable blade should be provided with a rake to prevent excessive loading.

To provide a rake angle between the movable and stationary blades, the included angle between the cutting edges of the upper or movable blade is increased to 95°, as shown in Fig. 8(b). Shearing begins at the extremity of each leg and progresses toward the root of the angle. The increase in the included angle of the movable blade results in some distortion of the drop-cut piece; the amount of distortion is approximately equal to the difference in angle between the movable and stationary blades (5° is normal). The part remaining on the table or stationary blade is not distorted.

Fig. 7 Two types of blades for the shearing of bars. See text for discussion.

Fig. 8 Four types of blades for the shearing of angle sections. (a) to (c) Shearing in a combination machine. (d) Double-cutting method

Most combination shearing machines use a more versatile blade arrangement than those shown in Fig. 8(a) and (b). The setup shown in Fig. 8(c) is used to shear angle sections in both the leg-up and the leg-down positions. A swiveling table locates and holds the workpiece during shearing. With the swiveling table and two positions for the workpiece, the flanges can be easily mitered to any specific angle. For example, when shearing angle sections for a frame having the leg on the inside, the table would be set and locked at 45°. One end is mitered by placing the section in a leg-down position on the table and shearing off enough to make a clean cut. The other end is mitered by placing the section leg-up on the table and shearing to the proper length. The opposite positions are applicable when angle sections for a frame having the leg on the outside are being cut.

Shearing at a 45° angle reduces the capacity of the machine because a greater length of metal is cut at one time when a 90° cut is made. For example, a machine with a capacity of 200 by 200 by 32 mm (8 by 8 by 1¼ in.) when making a 90° cut has a capacity of only 200 by 200 by 25 mm (8 by 8 by 1 in.) when cutting at 45°.

**Double cutting of angle sections**, also called slugging, is used less frequently than shearing in a combination-type machine. This technique uses two stationary blades, spaced 13 mm (½ in.) apart, and one movable V-shaped blade arranged as shown in Fig. 8(d). The movable blade has a shallow V-shape that does not conform to the shape of the workpiece. Shearing starts at the extremity of each leg and progresses to the root of the angle, producing a 13 mm (½ in.) wide slug that is pushed out the bottom between the stationary blades.

In the double-cutting method of shearing, distortion occurs only in the slug, because the work metal is supported by the two stationary blades. There are two disadvantages of using the double-cutting method. First, increased power is required for making two cuts at the same time, and second, some metal is lost in the slug. The two stationary blades must be firmly supported to prevent their spreading during the cutting operation.

A similar tool can be used for shearing a channel section. The stationary blades should closely fit the contour of the channel section. Double cutting is adaptable to a guillotine shear, a combination machine, or a press.

**Multiple Setups.** Fabricating shops often must shear small quantities to a variety of shapes. To handle such work, many shops use a machine with a multiple setup, such as the one shown in Fig. 9. Without changing blades, the following operations can be performed:

- Double shearing of angle sections (Fig. 9, left)
- Straight-blade shearing (Fig. 9, center)
- Shearing of round and square bars and single shearing of L-sections (Fig. 9, right)

In this type of setup, all movable blades are attached to a single ram.

**Fixturing** is an important consideration in the shearing of bars. For safety and the proper functioning of open-end machines (Fig. 5) and many other iron-working machines, holddown fixtures are essential. Guide pins are also helpful, especially when cutting with conforming blades such as those shown in the center and at the right in Fig. 9.

## Double-Cut versus Single-Cut Shearing

Two types of dies are used for shearing of structural and bar shapes: double-cut dies and single-cut dies.

**Double-Cut Shearing.** In shearing with double-cut dies, the shear blade acts as a punch and has a die on either side of it. A thin slug is sheared or punched out of the bar, its width depending on the size of the shear roughly as follows:

Shears with capacities of:		Slug (blade) thicknesses of:	
kN	tonf	mm	in.
160	18	10	3/8
445	50	13	1/2
1300	150	20	3/4

Double-cut shearing has three advantages. First, it produces distortion-free cuts on shapes that can be closely matched to the contour of the dies and where the surface in contact with the blade varies in shape. For example, angle iron and channel iron have square outside corners that can be closely matched by the dies, but the inside fillets vary with size. Respective fillet radii for various angle-iron dimensions are as follows:

Angle-iron dimensions		Fillet radius	
mm	in.	mm	in.
50×50×6	2×2×1/4	5	3/16
100×100×6	4×4×1/4	10	3/8
150×150×13	6×6×1/2	13	1/2
200×200×20	8×8×3/4	16	5/8

Both ends of a sheared angle or channel have the same square, burr-free quality after being double cut. Double cutting does not improve the quality of flat-stock, round-stock, or square-stock shearing.

Second, shearing forces are greatly reduced due to the rake angle on the blades. The angle-iron shear blade has a 120° included angle, which results in a 15° effective rake angle per side. Table 3 gives a comparison of the forces required for double-cut and single-cut shearing. The rake angle on the blade badly distorts the slug, which is thrown away. Flat stock is double-cut sheared to increase the capacity of the shears.

Capacities of double-cut dies are determined primarily by stock thickness, but there is a limit on the bar width or flange size. With the rake angle, only a small area is being sheared at a time; therefore, the only way to increase that area is to increase the bar thickness. For example, a 160 kN (18 tonf) shear will cut 100 by 100 by 6 mm (4 by 4 by ¼ in.) angle iron but will not

cut 50 by 50 by 10 mm (2 by 2 by ¾ in.) angle iron even though its total area is smaller.

The third advantage of double-cut shearing is that no holddown is required to keep the material from “kicking” up. The blade holds the material firmly against the dies, which creates a balanced condition. The material must span the two dies, and a minimum length equal to the stock thickness must be cut off to prevent damage to the blade or dies.

**Single-Cut Shearing.** In shearing with single-cut dies, the material is sheared by two opposed cutting surfaces that closely pass by one another—as in, for example, a pair of scissors or a typical mechanically driven universal shear. Nondistorted cuts are possible only where both the upper blade and lower die match the contour of the bar. For example, flat bars are cut free of distortion when the upper blade closely parallels the lower die. If a rake angle were applied to the blade, it would distort the part in contact with the blade; however, the other side of the cut in contact with the die would be free of distortion. Round and square bars are always single cut. Flat bars are usually single cut but may be double cut for increased size capacity. Angle iron must be double cut for best nondistorted cuts but can be single cut if distortion is not a problem.

Single-cut shearing causes distortion of angle iron mainly because of the mismatch between the radius on the blade and the fillet size in the angle. The fillet size varies with the angle size, as noted previously. Single-cut shearing requires a hold-down ahead of the die and, for best results, a support on the opposite side. Figure 10 illustrates

Fig. 9 Multiple setup for various types of shearing—singly or in combination

Table 3 Forces required for single-cut and double-cut shearing of angle iron

Size of angle iron(a)		Required force			
		Single cut		Double cut	
mm	in.	kN	tonf	kN	tonf
100×100×6	4×4×1/4	535	60	130	15
150×150×13	6×6×1/2	1560	175	355	40
200×200×19	8×8×3/4	3070	345	1245	140

(a) A-36; shear strength, 415 MPa (60,000 psi)

the importance of a holddown and a support. The support is not required on single-cut angle-iron dies due to the shape of the bar, which prevents it from bending. A fixed support, as shown, is satisfactory, provided that the part being sheared is sufficiently long (approximately 150 mm, or 6 in., on 445 kN, or 50 tonf, shears). Shorter parts can be sheared if a spring-loaded support pad is used. The new style of round-stock dies used in four-post injector-type shears do not require a support due to their unique design, which is explained later.

## Nondistorted, Burr-Free Cuts

Figure 11 illustrates what is meant by the phrase "nondistorted, burr-free cut." Normal deformation on the opposite side contacting the die still exists due to the inherent shearing characteristics of materials. The amount of deformation depends on the hardness of the material: The harder the material, the less severe the deformation. The amount of "break" depends on the thickness and type of material.

## Shearing of Specific Forms

**Shearing of Angle Iron.** Angle iron can be sheared with double-cut or single-cut dies. Figure 12 shows a double-cut die and how it can be used to miter angle iron up to 45° and cut square tubing and flat stock. This die will also cut small bar-sized channels where flange height does not exceed 14 mm (9/16 in.). The versatility of this assembly, plus the fact that a holddown is not required, makes it extremely popular.

Square tubing can be cut with little distortion, provided that the wall thickness in proportion to the tube size is great enough to withstand the shearing force. The angle-iron blades normally have a large radius on the point, but in shearing of square tubing, it is best to use a pointed blade.

The type of material has a large effect on the quality of cutting.

Shearing of flat stock in a double-cut angle die creates a side thrust that is taken by blade guides. For this reason, it is best to cut two bars at once, one on each side; in high production, it is best to use a flat-stock die designed for that purpose.

The clearance between the blade and the dies must be adjusted to suit the angle-iron thickness. This is accomplished by inserting spacers behind the die inserts or holders. No spacers are required on 160 kN (18 tonf) shears, one set on 400 and 445 kN (45 and 50 tonf) models, and two sets on 1330 kN (150 tonf) models.

Single-cut angle dies are limited to angle-iron cutting. Figure 13 shows an injector-type die with a manually adjusted holddown on the feed side of the machine. The holddown must be adjusted so that the material clears by only 1.6 mm (1/16 in.). An air-operated holddown is used with feed systems that have a lift under the conveyor for lifting the material off the die

during the feed cycle. The radius on the single-cut angle shear blade is of an intermediate size so that it can be used to cut a range of angle sizes with minimum distortion.

**Shearing of Flat Stock.** Figure 14 illustrates the double-cut flat-stock tooling assembly for a 1330 kN (150 tonf) shear. Note the concave rake angle on the leading face of the blade. Its concave shape balances the material through the center of the die.

The single-cut flat-stock die looks similar to the double-cut die except that the blade does not have a severe rake but a mere 31.2 mm to the meter (3/8 in. to the foot). This rake goes straight across the blade and causes little or no distortion. If absolute flatness on the part is required, the blade should not have a rake angle. The 160 and 400 kN (18 and 45 tonf) shear models have no rake.

**Shearing of Round, Hexagonal, and Square Bars.** Figure 15 illustrates the type of die used in the 160 and 400 kN (18 and 45 tonf) shear models. Five die cavities are provided—three for round bars, one for hexagonal bars, and one for squares. The die cavity is made to fit the bars very closely for minimum distortion, and therefore, this die is limited to shearing of five bar sizes in

Fig. 11 Typical quality of cuts made by hydraulic shears. Dimensions given in inches

Fig. 10 Single-cut shearing of flat, round, and square bars, showing holddown and support required for nondistorted cutting

Fig. 12 Double-cut angle die for cutting various shapes without changeover

Fig. 13 Single-cut angle die with adjustable holddown

Fig. 14 Double-cut tooling assembly for cutting flat stock and bar stock

the shapes noted. The die cavity or hole for cold-finished round bars is 0.05 to 0.10 mm (0.002 to 0.004 in.) larger than the bar. After the bar has been sheared, it will still freely slip back through the hole, which points out how little the bar is distorted. Hexagonal and square bars can be sheared with the same accuracy. Smaller squares can be sheared with good success using a larger die cavity, provided that a holddown is added to the front of the machine. Normally, the die itself acts as a holddown, because it completely confines the bar.

The single-cut blade shown in Fig. 15 has only a half-hole to fit over the bar and must be used with a rear support. This blade is simple in design and inexpensive. Figure 16 shows a round-stock die for use in injector-type shears. This type of die features interchangeable bushings to suit the bar being sheared. Two identical bushings are used: One is for the fixed die, and the other fits into a moveable slide, forming what is normally called the blade. Three bushing sizes (outside diameter) are used to cover a range of bar diameters up to 63 mm (2½ in.) in the 1330 kN (150 tonf) shear. The reason that there are three sizes is cost, because they are perishable. The 197 mm (7¾ in.) die height (feed-conveyor height) is maintained only when the bar or hole size for each of the three bushings is at a maximum. Therefore, the height increases slightly when going to smaller bar.

The round-stock die in Fig. 16 has a spring-loaded slide that can be set in the open position to very precisely align the front and rear die bushings for feeding. Bars are sheared in less than a second as the ram forces the slide down, offsetting the bushings. Hexagonal and square bushings can be made for those shapes. A hold-down is used on the larger bars due to the high amount of torque involved.

As cited previously, cold-finished round bars are closely fit to the die hole within 0.05 to 0.10 mm (0.002 to 0.004 in.), but hot-rolled bars need more clearance due to their oversized, out-of-round, scaly condition. Usually 0.8 mm (⅓ in.) is allowed for bars up to 32 mm (1¼ in.) in diameter, and 1.6 mm (⅙ in.) for bar diameters up to 63 mm (2½ in.).

**Shearing of Channel and I-Sections.** Channel iron and I-sections are difficult to shear without distortion, mainly due to the mill toler-

**Fig. 15** Single-cut shearing die for cutting round, square, and hexagonal stock in two-post shears

ance that allows their width to vary, depending on size, by as much as 5 mm (⅜ in.). On the other hand, Fig. 17 shows how a channel is cut in a double-cut die, which supports it on three sides. The "W"-shaped blade shears the flanges outward against the inserts. This die automatically, through hydraulics, causes the side inserts to move in and clamp the channel prior to contact by the blade. After the cut, when the blade starts to ascend, the inserts unclamp and move approximately 5.5 mm (7/32 in.) to allow the channel to be fed through the die.

One channel die assembly cuts a range of sizes. For example, a 1330 kN (150 tonf) shearing die cuts American Standard tapered flanges and Ship and Car channels in sizes from 75 to 250 mm (3 to 10 in.). To adjust from one size to the next, the clamping cylinder located on the side of the shear (Fig. 18) is disengaged, and a lever is

**Fig. 16** Round-stock die assembly for four-post shear, featuring interchangeable bushings

**Fig. 17** Double-cut tooling assembly with adjustable die for nondistorted shearing of channels and I-beams

turned to move the inserts in or out. Right- and left-hand screws are rotated simultaneously through a line shaft that keeps the inserts always centered about the blade.

Two shear blades are used to cut the 75 through 250 mm (3 through 10 in.) American Standard channel sizes. One cuts 75 to 125 mm (3 to 5 in.) channels, and the other cuts 150 to 250 mm (6 to 10 in.) channels. Changing the blades takes only 30 s.

I-beams are cut in the channel die by changing the lower die inserts and sometimes the blade. Figure 17 illustrates how the inserts are made higher to fit up into the "I" for supporting the web sections. A set of two lower inserts is required for each size of I-section, but in some cases, one shear blade will cut more than one size.

The 160 and 400 kN (18 and 45 tonf) shears use fixed dies for cutting channels, as shown in

**Fig. 18** Shearing die with hydraulic cylinder that clamps channel for distortion-free shearing

Fig. 19. These allow the flanges to spread, causing distortion, and the stock cannot be fed as easily as in the dies described previously. Fixed channel dies are not recommended for high-production shearing.

**Shearing of T-Bars.** T-bars are sheared in double-cut angle-iron dies by using a special set of side inserts, as shown in Fig. 20. The angle-iron shear blade is used. Stroke is the limiting factor when determining shearing capacity:

- A 160 kN (18 tonf) shear will cut T-bars up to 38 by 38 by 5 mm (1½ by 1½ by 3/16 in.).
- A 400 kN (45 tonf) shear will cut bars up to 63 by 63 by 6 mm (2½ by 2½ by ¼ in.).
- A 445 kN (50 tonf) shear will cut bars up to 75 by 75 by 10 mm (3 by 3 by 3/8 in.).
- A 1330 kN (150 tonf) shear will cut bars up to 100 by 100 by 13 mm (4 by 4 by ½ in.).

A slight amount of distortion can be expected in the web due to shearing.

Fig. 19 Fixed channel die for two-post shears

Fig. 20 Double-cut angle-iron die assembly with side inserts for shearing of T-bars

Fig. 22 Dual-height system with fixed V-rolls and movable flat rolls

**Shearing of Z-Bars.** Structural Z-bars are single cut with a special die designed for that purpose. The blade and insert must be made to match the Z-bar contour; however, due to the mill tolerance, some distortion can be expected. Only the 445 and 1330 kN (50 and 150 tonf) shears are adaptable for shearing of Z-bars, and a special holddown is required (Fig. 21).

Structural Z-bars cannot be double cut due to their great thickness. Light-gage roll-formed Z-purlins, used in the metal building trade, have to be double-cut sheared.

## Materials Handling

Materials handling and gaging have presented problems with many of the commonly used universal shears. Materials handling on some shears constitutes 95% of overall cost. Thus, inexpensive shear cutting can be very costly if feeding and gaging of the material are not done efficiently. If the shear machine has different die locations and feed and stop heights, it may be very difficult to equip this shear with a feed and stop system that will result in fast cutting to length. With hydraulic bar shears, a common feed conveyor and stop (that readily adapt to the various bar shapes) reduce the materials-handling costs and the overall shearing cost to a minimum.

Because four-post injector-type shears are normally used for production cutting, their feed systems are discussed; however, much is applicable to other models.

Two die heights are used on four-post shears: one for angle iron; and the other for flats, channels, rounds, and other shapes. Figure 22 shows how a dual-purpose conveyor is made to adapt to the two die heights and provide positive align-

ment for the bars. The Y-rolls are permanently mounted to the conveyor base for guiding of angle iron. The other dies, for flats and channels, are 38 mm (1½ in.) higher, which makes it convenient simply to raise the flat rolls to allow the material to pass over the V-rolls, as shown at left in Fig. 22. The right-hand view shows the flat roll in the lowered position.

A cut can be no squarer than the guiding system. Thus, the V-rolls for angles maintain positive alignment for both single- and double-cut dies. Adjustable side guides must be set for guiding the other shapes, such as flats and channels. Whether powered or manually fed, the cut-to-length system greatly reduces shearing costs and increases production.

**Hydraulic shears** lend themselves to many nonstandard applications. One such case is illustrated in Fig. 23, which shows how a 160 kN (18 tonf) shear for cutting angle iron up to 100 by 100 by 6 mm (4 by 4 by ¼ in.) is used in line with a hydraulic modular gang punching machine. This approach to metal fabrication is a prime example of how operations can be grouped to reduce material handling.

Another example of a nonstandard application, which required only a special die assembly, is shown in Fig. 24. Here, a 150 mm (6 in.) wide flat bar is sheared, leaving one end with a large radius and the other end with a slot. Three operations were combined into one, producing significant savings in labor.

These are only two of many applications that prove the versatility of hydraulic shears. These shears can also be used for forming, notching, punching, riveting, and many other operations. The four-post shear has a large tooling area and is adaptable to many different applications, with the main limitation being imagination.

Fig. 21 Single-cut die assembly for shearing of Z-bars

Fig. 23 A 160 kN (18 tonf) shear mounted at 45° angle for use with gang punching machine

The advantages of hydraulic bar and structural shears are:

- Reduced setup, tooling, and running costs: quick-change tooling for all shapes; long tool life—no shock; fast, efficient feeding; only one operator required
- Ease of materials handling: common feed line for all shapes; powered feed available; back gage and conveyor provide efficient takeaway
- Improved quality of cut: little or no distortion; no burrs; square cuts gaged to close length tolerances
- Elimination of secondary grinding operation to remove burrs
- Reduced physical strain
- Increased production
- Increased versatility (shearing, forming, notching, punching, riveting, etc.)

## Impact Cutoff Machines

Impact cutoff machines produce high-quality cut slugs or blanks of precise length from round, square, or specially shaped bars or coils. Two precision cutoff dies are engaged in opposite directions within the impact block, with short, simultaneous strokes fracturing the metal. The result (Fig. 25) is a clean cut at the interface of the two dies, producing slugs or blanks with length tolerances of well within  $\pm 0.13$  mm ( $\pm 0.005$  in.) and virtually no deformities at reduction speeds of 300 cuts per minute.

The quality of cut obtained surpasses that produced by any other known shear-type cutoff device. Squareness is held to close tolerances, and the cut pieces are virtually free of burrs, distortion, and edge rollover.

On materials such as carbon steel of 415 MPa (60 ksi) tensile strength, impact cutoff machines are capable of cutting 65 mm (2½ in.) diameter stock up to 915 mm (36 in.) long. Doubling the tensile strength of the material to 820 MPa (120 ksi) reduces the maximum diameter capacity to 45 mm (1¾ in.).

**Principle and Machine Construction.** Impact cutoff machines use a unique double-impact cutting principle (Fig. 26). Stock is fed into a pair of precision cutoff dies that have a cavity shaped to the same configuration as the stock. These opposed dies are actuated with short, simultaneous strokes by two flywheel-cam assemblies. This double impact fractures the

**Fig. 24** Shaped blade and die that produce radiused and slotted ends with each stroke

metal, cleanly cutting the confined stock at the interface of the two dies.

The cutoff dies are located within an impact block. The flywheels rotate at a constant speed, and a cut takes place only when a pair of air-operated wedges are brought into position to close the gap. Wedge elevation is triggered by a positive stop that controls the length of cut. The

positive stop features a micrometer adjustment for precise control of the blank length.

Either a short or a long target—stock-stop or length gage—is used, depending on the length of cut. In actual operation, the target moves out of the way when the leading edge of the workpiece engages it. This motion activates the circuit that controls the wedges to make the cut. Stock is fed

**Fig. 25** Effects of shearing a round bar with double-die impact cutoff-type shear

**Fig. 26** Impact cutoff machine shearing bar stock with twin cutoff dies that are actuated by cam rollers on identical flywheel-cam assemblies

into the dies and up to the positive stop by a hydraulically driven roll feed.

**Die life** is excellent in impact cutoff machines and ranges from tens of thousands to hundreds of thousands of cuts before resharpening is required. A number of variables affect this, with the most important being the amount of clearance between the workpiece and the die.

The dies are usually of the inserted type. The longest service life has been obtained with

inserts made of M2 high-speed steel hardened to 60 to 62 HRC.

When resharpening of the cutoff die is required because of wear, the insert is first removed and then replaced in the holder with a 0.5 mm (0.020 in.) shim behind it. The protruding portion of the insert is then sharpened by a simple surface grinding operation. Removing the die blocks for sharpening or replacement is fast and simple. The die-retaining plate

unbolts, allowing the cutting dies to be easily lifted out.

#### ACKNOWLEDGMENT

This article was adapted from *Forming and Forging*, Volume 14, *Metals Handbook*, 9th ed., ASM International, 1988, p 714, and from O.D. Lascoe, *Handbook of Fabrication Processes*, ASM International, 1988.

# Bending of Bars and Bar Sections

ROD AND BAR may be bent in the same manner as tubing. The possibility of collapsing or wrinkling is eliminated, because the solid section provides its own internal support. Generally, rod and bar in the annealed condition are preferred for cold forming. Material in other tempers may be required for some forming operations or when properties that cannot be obtained by heat treatment after forming are desired in the end product.

## Bending Methods

Bending of bar and other nontubular sections involves similar techniques to that of tubing, although tube bending may require additional supports inside the tube (see the article "Bending and Forming of Tubing" in this Volume). Methods common to the bending of bar or tubes include draw bending, compression bending, roll bending, stretch bending, and ram-and-press bending. Bending methods unique to pipe or tube include wrinkle bending and roll-extrusion bending.

**In draw bending,** the workpiece is clamped to a rotating form and drawn by the form against a pressure die (Fig. 1a). The pressure die can be either fixed or movable along its longitudinal axis. A fixed pressure die must be able to withstand abrasion caused by the sliding of the work metal over its surface. A movable pressure die, because it moves forward with the workpiece as it is bent, is less subject to such abrasion. It provides better guidance and more uniform restraint of the work material. Draw bends are made when more precise dimensional tolerances are needed, or when tight bends of thin-walled tubing are required (see the article "Bending and Forming of Tubing" in this Volume). Bends up to 180° can be made. Draw bending is more common than any other bending method when power bending machines are used.

**In compression bending,** the workpiece is clamped to a fixed form, and a wiper shoe revolves around the form to bend the workpiece (Fig. 1b). Compression bending is most useful in bending rolled and extruded shapes. A bend can be made close to another bend in the workpiece without the need for the compound dies required in draw bending. Although compression bending does not control the flow of metal as well as draw bending, it is widely used

in bending presses and in rotary bending machines.

The fixed form may have a flat surface or be contoured to match the diameter of the workpiece. When the radius block is contoured, a stop plug may be used instead of a clamp. Clamping is often necessary when bar stock is being bent against a flat radius block. The action of the roller on the stock is sometimes through a wiper shoe. The wiper shoe converts the single fixed load of the roller into a uniformly distributed load on the stock.

**Roll bending** uses three or more parallel rolls. In an arrangement using three rolls (Fig. 2a), the axes of the two bottom rolls are fixed in a horizontal plane. The top roll (bending roll) is lowered toward the plane of the bottom rolls to make the bend. The three rolls are power driven; the top roll is moved up or down by a hydraulic cylinder. Another roll arrangement is four-roll bending (Fig. 2b). The bar enters between the two powered rolls on the left. The lower bending roll is then adjusted in two directions according to the thickness of the bar and the desired angle of bend.

Rings, arcs of any length, and helical coils are easily fabricated in a roll bender. The bend radius usually must be at least six times the bar diameter or the section thickness in the direction of the bend. To limit distortion in the roll bending of asymmetrical sections, a double section can be made and split in two after bending. Rings are sometimes made by roll bending coils and

cutting them into rings for welding. A typical roll bender with three driven rolls is shown in Fig. 3. Roll benders may also be manually powered (Fig. 4).

Roll bending is impractical for making more than one bend in a bar. It is difficult to control springback in a roll bender, and it may take several passes through the rolls to make the needed bend. Therefore, this method of making bends is slower than other methods. Another disadvantage of roll bending is that a short section of each end of the bar is left straight. For three-roll bending, the ends can be preformed in a press before bending, or the straight parts can be trimmed off. The following example describes a production application of three-roll bending. Other examples of three-roll bending are covered in the article "Three-Roll Forming" in this Volume.

**Example 1: Three-Roll Bending of a Structural Section.** A 7.6 kW (10 hp) three-roll bender was used to bend a steel angle 75 by 75 by 9.5 mm (3 by 3 by 3/8 in.) into a circular reinforcing flange 1520 mm (60 in.) in diameter. The angle was of hot-rolled ASTM A107 steel. The top roll of the bender was a plain cylinder; each of the two bottom rolls consisted of two cylindrical sections held apart by a spacer to provide a recess for the edge-bent flange.

Fig. 1 Essential components and mechanics of (a) draw bending and (b) compression bending of bars and bar sections

Fig. 2 Operating essentials in (a) one method of three-roll bending and (b) four-roll bending

The operations were performed in the following sequence:

- Cut angle to developed length plus 254 mm (10 in.)
- Set rolls to bend correct radius; roll 360°
- Cut off ends of the rolled bar
- Weld the bar into a ring
- Grind the weld flush
- Roll the ring in the three-roll bender to make it a true circle

**Stretch bending** is used for bending large, irregular curves. The workpiece is gripped at its ends and bent as it is stretched around a form (Fig. 5). The gripped ends are customarily trimmed off. This method can accomplish in one operation what may otherwise take several operations for parts with compound curvatures or large parts with shallow curvatures. The result is a possible savings in time and labor, even though stretch bending is a slow process. Tooling and machines may also be more costly, because stretch forming is a relatively sophisticated operation.

One benefit of stretch forming is that it elongates the metal throughout the section (Fig. 6a). This differs from the other methods (draw bending, compression bending, press bending, and roll bending) that result in some compression in various sections of the bend (Fig. 6b). Thus, less springback occurs when the work is stretched formed, due to the lack of compressive strain. Wall thickness is generally reduced but with greater uniformity.

**Fig. 3** Roll bender with three driven rolls and hydraulic positioning of the top roll. Courtesy of Baileigh Industrial Inc.

**Ram-and-Press Bending.** With this method, a workpiece is placed between two supports, and a rounded form die (ram or punch) is pressed against it (Fig. 7). The two supports pivot as the ram moves forward, maintaining support of the workpiece. The two supports may be fixed or allowed to pivot. This method is rapid but provides less control over metal flow. It is used in production applications on heavy sections, depending on the capacity of the available press. Most ram benders are driven hydraulically, and they are commonly used to bend tube but are also used to bend solid sections.

**Fig. 5** Principle of stretch bending

## Bending Machines

The machines used for the bending of bars include the following: devices and fixtures for manual bending, press brakes, conventional mechanical and hydraulic presses, horizontal bending machines, rotary benders, and bending

**Fig. 6** Strain distribution for section formed by (a) stretching and (b) bending. Draw bending, compression bending, press bending, and roll bending compress the metal in various sections of the bend. Stretch bending imparts elongation throughout the bend and thus minimizes springback.

**Fig. 7** Ram-and-press bending. (a) General configuration. (b) Tool area

presses. Shapers have also been used to perform specific bending operations.

**Manual Bending.** Hand-powered machines or fixtures are used in many shops for making bends that do not require much energy to form. This equipment is supplied with ratchets, levers, or gears to give the operator mechanical advantage. Different types of fixtures are used for manual draw bending, stretch bending, or compression bending. Roll bending is seldom done by hand. The tools used in manual bending are the same as those used on some power bending machines. The maximum sizes of low-carbon steel bars that can be manually cold bent are given in Table 1.

**Press brakes** are used for all types of bending, especially in small-lot production (25 to 500 pieces), when standard tooling or low-cost special tooling can be used. Often, the punch is not bottomed in the die, but the stroke is controlled, and the bar is bent “in air” (Fig. 8). With this technique, various bend angles can be made with the same die (see also the article “Press-Brake Forming” in this Volume).

**Mechanical presses** are generally used only for mass production, because only large production lots can justify the cost of tooling, which is more than that for most standard bending tools. Figure 9 shows a round bar being bent into a U-bolt in a press. The bar is first cut to length and pointed at both ends (preliminary to a later threading operation). The bar is then loaded into the press and held in a grooved die that bends the bar into a “U” in one stroke. In the setup shown in Fig. 9, more than one workpiece can be bent at a time. The following example describes an application of a mechanical press in bending bars.

Table 1 Maximum sizes of low-carbon steel bars for manual bending

Shape	Size mm (in.)
Rounds	25 (1) (diam)
Squares	19 (¾) (per side)
Flats bent on flat	9.5 × 102 (⅜ × 4)
Flats bent on edge	6.4 × 25 (¼ × 1)
Angles	4.8 × 25 × 25 (⅜ × 1 × 1)
Channels	4.8 × 13 × 25 (⅜ × ½ × 1)

Fig. 8 Air bending of a bar in a press brake

**Example 2: Bending a Welded Assembly in a Mechanical Press.** The wheel spider shown in Fig. 10 had three 255 mm (10 in.) long spokes of 9.52 mm (0.375 in.) diameter low-carbon steel. The spider was assembled by welding the three spokes to a 13 mm (½ in.) thick steel hub. The assembly was loaded into a 670 kN (75 tonf) mechanical press, a double bend (joggle) was made in the spokes, and the short straight surface between the two bends was flattened to 6.4 mm (¼ in.) thick. The wheel rim was then welded to the spokes, as shown in Fig. 10(d). Next, the assembly was loaded into another press, in which the legs were sheared flush with the outer edge of the rim, and a 3.2 mm (⅛ in.) diameter hole was pierced in the flattened area of each spoke. The production rate was 25 per minute.

**Hydraulic presses** are often used to bend bars in much the same manner as mechanical presses. Although hydraulic presses are usually slower than mechanical presses, they have the advantage of exerting full force over a long stroke. Therefore, deep bends can often be made on a hydraulic press much smaller than the mechanical press that would be required. In the following example, a hydraulic press needed so little head room that a closed shape could be bent over it.

**Example 3: Bending a Double-Bar Structure in a Hydraulic Press.** A double-bar structure was constructed of two 11 mm (7/16 in.) diameter bars that were connected by welded cross members to form a ladderlike structure. A rectangular shape was formed by making four 90° bends having 16 mm (5/8 in.) inside radii. The two bars (sides of the ladderlike structure) were bent simultaneously, using a punch that forced the bars between rollers. By using a small (27 kN, or 3 tonf) vertical hydraulic press, the four bends could be made consecutively, allowing the workpiece to encircle the press ram as bending was completed. The overhead clearance

Fig. 9 Use of a grooved die in a mechanical press for bending a round bar into a U-bolt in one stroke

would not have been available with a mechanical press. This technique permitted the fabrication of 360 double bends (90 frames) per hour.

**Horizontal bending machines** for bending bars consist of a horizontal bed with a powered crosshead that is driven along the bed through connecting rods, crankshaft, clutch, and gear train. Dies are mounted on the bed, and forward motion of the crosshead pushes the bar through the die. The long stroke and generous die space make this machine useful for a variety of cold and hot bending operations, although speeds are lower than those for mechanical presses of similar capacity. Horizontal benders are available in capacities from 89 to 2700 kN (10 to over 300 tonf).

**Rotary benders**, either vertical or horizontal, are used for the draw, compression, or stretch bending of bars. Such machines consist of a rotary table in either a horizontal or vertical position on which the form block or die is mounted (Fig. 1). Suitable hydraulic or mechanical clamping, tensioning, or compressing devices are provided to hold the workpiece while the die rotates to the required position, or while the workpiece is bent about the central forming die. Some machines can make bends by two, or all three, methods. This type of bender is often built for manual bending of tube or pipe. A programmable rotary bender with a universal bending plate is shown in Fig. 11.

**Bending presses** are most widely used for bending tubing because of the wide variety of techniques and tooling options. However, bending presses are occasionally used for bending bars, as in the following example.

**Example 4: Making a Double Crank in a Bending Press.** Double cranks, such as the one shown in Fig. 12, were made in a bending press from round bars 8 or 9.5 mm (5/16 or 3/8 in.) in diameter. The bars were cut to length and fed into the press to flatten the ends and pierce the holes. The two sharp bends were made one at a time in

Fig. 10 Welded bar assembly that was formed by bending in a mechanical press. Dimensions given in inches

the same press with a V-die. A bearing bracket was assembled on the crank, followed by a double-staking operation in the same press. The greatest demand on the press was in the end-flattening operation, which required a press capacity of 890 to 1330 kN (100 to 150 tonf).

**Shapers** can be tooled for bending operations. One method is to have the fixed die, or anvil, held on the knee of the shaper and the punch mounted on the ram (Fig. 13). The shaper must make one stroke only. The stroke can be adjusted to allow for springback in the workpiece; therefore, the workpiece can be bent to fairly close limits.

The setup shown in Fig. 13 is used to correct for springback in formed parts such as J-bolts, U-bolts, and rings. A V-punch and die mounted in the shaper can make bends of various kinds.

A shaper can also be provided with a rack and pinion to produce rotary motion for bending (Fig. 14). Bend radius can be varied by the use of center pins of different diameters. A typical use of a shaper in the bending of bars is described in the following example.

**Example 5: Shaper versus Press for the Bending of J-bolts.** Originally, J-bolts were press bent cold in a die from sheared lengths of 13 mm ( $1/2$  in.) diameter hot-rolled merchant bars of 1025 steel. The press made the J-bolts by bending the bar into a half circle with one long arm. Because the unbalanced support caused variations in bending, some of the parts were unacceptable.

The job was put on a shaper. For this operation, the stock was sheared to double lengths, which the shaper bent into a circular loop with two long arms (the ends). The looped bar was then sheared in half. The cost of tooling for the shaper was much less than that for the press.

A rack-and-pinion-actuated fixture similar to that shown in Fig. 14 was used to bend the bar into a circular loop. The bar stock was placed in the fixture at a slight angle to allow one leg to pass the other during forming. After the bar was cut in two, the J-bolt was finished in a setup such as that shown in Fig. 13.

## Tools

Tools for draw and compression bending are shown in Fig. 1. The form used in both processes is shaped to fit the work. Often, the form is part of a right cylinder whose straight portion (frequently, an insert) provides the surface against which the work is clamped. Hydraulic or mechanical pressure holds the clamp against the workpiece. Annular grooves or roughened surfaces grip the bar or bar section.

To allow for springback, the bend radius is made smaller on the form than is required for the workpiece. The form is also designed for a greater angle of bend than is needed. These two adjustments permit overbending the piece to allow for springback. Such adjustments are made by trial and error. The form is tested and corrections are made before it is heat treated.

The finish on the form (rotating or fixed) should be just good enough to avoid marring the workpiece. For most bar bending, a machined finish is sufficient. For decorative stainless steel and polished aluminum, grinding or polishing of the form surfaces may be needed. However, the clamping area should not be ground or polished unless necessary. The smoother the finish in the clamping area, the greater the danger that the workpiece will slip through the clamp. The

pressure die and wiper shoe require a good finish (usually ground) because the work metal must slide along them.

When air bending bars in a press brake, simple V-blocks will suffice for the female dies. The opening of the V-blocks should be eight times stock thickness for standard sections, and ten times stock thickness for heavy sections. The upper die (punch) is shaped to the inside radius of the bend, and the angle of bend is controlled by the length of stroke. The same die set can be used for making various bends, as well as for various stock thicknesses, by adjusting the stroke.

Press brakes can use rubber pads for tooling on bends that need support (see the article "Press-Brake Forming" in this Volume). Completely shaped dies for bottoming can also be used in a press brake, as shown in Fig. 15.

Fig. 15 Die setups in a press brake for (a) edge bending a bar and for (b) bending two structural angles

Most dies used in conventional mechanical or hydraulic presses are completely shaped bottoming dies, which makes them more expensive than tooling for other bending machines. Tooling for bending presses is specially designed to fit the needs of the machine and the work to be done. Dies for bending presses are simple to construct and relatively inexpensive. Tools for stretch bending are covered in the article “Stretch Forming” in this Volume.

**Die Materials.** Dies are usually made of hardened steel for the production of thousands of pieces per month. Tool steel is used for small one-piece dies. Larger dies are made of low-carbon steel and then carburized and hardened. Clamping inserts are made separately.

For moderate production of a few hundred pieces per month, unhardened carbon steel is often used. If only a few parts are needed, wood or an aluminum alloy may be strong enough for dies.

For bottoming dies in presses, hardened tool steel is always used. For cold bending, A2 tool steel hardened to 58 to 62 HRC is most often selected. A hot work tool steel, such as H11,

Table 2 Typical lubricants for bending various metals

Work metal	Lubricant
Low-carbon steel	Water-soluble, vegetable-oil based drawing oil(a)
Stainless steel and other high-alloy iron-base alloys	Mineral-oil-based drawing oil(a)
Aluminum alloys and copper alloys	Mineral oil
Brass (severe bends)	Soap solution(b)
Hot bending of carbon, alloy, and stainless steels	Molybdenum disulfide

(a) Available as proprietary material. (b) Creamy mixture of laundry soap and water

hardened to 45 to 50 HRC is usually the choice for hot bending.

Bend Allowance

The stock consumed in a bend (that is, overall length of a bend) can be computed from the radius of curvature at the neutral axis and from the angle of the bend. A formula often used for this computation is:

W=0.01745 α (r + δ)

where W is the bend allowance, α is the angle of bend (in degrees), r is the radius of bend to inner stock surface, and δ is the distance from the inner surface to the neutral layer (a commonly used approximation when this figure is not known is one-third to one-half stock thickness). The constant 0.01745 is a conversion factor changing degrees to radians.

When bar stock for a workpiece whose ends are within, or very near, the bend area is cut square to the neutral axis, the ends, after forming, will not be square to the neutral axis. The basic reason for this is the difference in circumference of the outer and the inner surfaces of the bend. Additional deviation from squareness can be expected because all of the material toward the outside of the bend from the neutral axis has undergone a tensile load, and the material inside

this line has been under compressive load. Unless compensation can be made for these variations, the ends of the formed part must be trimmed if they are to be square to the axis. However, when end details, locating surfaces, and other considerations necessitate such action, it is still possible to cut the blanks to size in such a way that trimming after forming is eliminated.

Lubrication

Successful bending depends to a large extent on the type of lubricant used. No one lubricant works equally well on all materials. Selection of a lubricant varies among different shops. Typical lubricants for bending specific metals are listed in Table 2.

Overlubrication, in either quantity or type of lubricant, must be avoided. Not only is excessive lubrication likely to cause wrinkling, but the cost of removal must be considered. It is never good practice to use a pigmented compound if successful results can be obtained with an unpigmented compound, because pigmented compounds are more difficult to remove.

Wiper dies are lubricated with a very small quantity of high-grade drawing lubricant. It is important not to overlubricate pressure dies and wiper shoes.

# Bending and Forming of Tubing

THE PRINCIPLES for bending tubing are much the same as those for bending bars (see the article "Bending of Bars and Bar Sections" in this Volume). Two important additional features in the bending of tubes are that internal support is often needed and that support is sometimes needed on the inner side of a tube bend.

The wall thickness of the tubing affects the distribution of tensile and compressive stresses in bending. A thick-wall tube will usually bend more readily to a small radius than a thin-wall tube. Table 1 lists the minimum practical inside radii for the cold draw bending of round steel or copper tubing, with and without various supports against flattening and wrinkling.

## Selection of Bending Method

The four most common methods of bending tubing are basically the same as those used in the bending of bars: compression bending, stretch bending, draw bending, and roll bending. The method selected for a particular application depends on the equipment available, the number of parts required, the size and wall thickness of

the tubing, the work metal, the bend radius, the number of bends in the workpiece, the accuracy required, and the amount of flattening that can be tolerated. Two additional methods for pipe bending are wrinkle bending and roll-extrusion bending.

**Compression bending of tube** is similar to that for bar bending. One end of the workpiece is fixed in place relative to a stationary bending form, while a moveable shoe or roller compresses the section against the form. Figure 1 illustrates an example, where one end is fixed by a stop plug and the tube is bent around a fixed bending form. Compression bending requires much less clamping area than for draw bending because the work material is pressed against the stationary form by the pressure tool. The various types of pressure tools include: a static wiper shoe, and follower block, or a roller.

Compression bending of tubing is often performed on manually operated machines. Mandrels cannot be used in compression bending because the mandrel would have to move with the workpiece when it is wrapped around the form. Thin-walled tubing is not usually bent by this method. However, bend radii as small as

2.5 times diameter of thin-walled tubing can be obtained with internal support to prevent wrinkling. The normal minimum centerline radius for compression bends is 4 times the tubing diameter (Ref 1). Bends up to 170° can be made.

Compression bending results in less stretching on the outer surface of the bend than with draw bending. In compression bending, the neutral axis lies in the outer third of the bend so that less stretching occurs along the outer surface of the bend. In contrast, the neutral axis in draw bending occurs at the inner third of the bend section. Because less stretching occurs, compression bending is effective in the forming of coated tubing.

**Draw bending of tube** involves a rotating bending form that pulls the tube through a pressure and wraps the tube around the bending die (Fig. 2). The tube is fastened to the bending die by a clamp with sufficient pressure to allow pulling the tube around the die. Flattening during draw bending tends to be more severe than with compression bending, and so typical machines for draw bending pull the tube over a stationary mandrel. The pressure tool can be a roller, a sliding shoe, or a static shoe.

Draw bending is used widely for tube forming. It is a versatile method for bending to tight radii with better dimensional control than compression bending. Bends up to 180° can be made with tube diameters ranging from about 13 to 250 mm (1/2 to 10 in.). When power machines are required, the draw bending method is more commonly employed than by powered compression bending. Draw bending can be done on

**Table 1 Minimum practical inside radii for the cold draw bending of annealed steel or copper round tubing to 180°**

Radii can be slightly less for a 90° bend, but must be slightly larger for 360°.

Tubing outside diam		Minimum practical inside radius					
		Grooved bending tools				Cylindrical bending block without mandrel; ratio, <30(a) (poor conditions)	
		With mandrel; ratio, <15(a) (best conditions)		With mandrel or filler; ratio, <50(a) (normal conditions)			
mm	in.	mm	in.	mm	in.	mm	in.
3.2	1/8	1.6	1/16	6.4	1/4	13	1/2

75	3	41	1 5/8	48	1 7/8	...	...
89	3 1/2	48	1 7/8	54	2 1/8	...	...
102	4	54	2 1/8	60	2 3/8	...	...

(a) Ratio of outside diameter to wall thickness of tubing

**Fig. 1** Tube bending around a stationary form with outside of tube held against a bearing block

manually operated machines (Fig. 3) or powered units for heavy pipe (Fig. 4). Close-fitting mandrels, dies, and shoes can be used to achieve bend radii as close as 1 diameter (Ref 1).

**Roll bending of tube** is limited to thick-walled product, but it is used to produce full circles of helical coils (see the article "Three-Roll Forming" in this Volume).

**Stretch bending of tube** may or may not involve the use of mandrel. Like stretch forming of bar, the advantage of this method is reduced springback, as the metal is stretched without compression in the inner part of the bend section.

**Ram-and-Press Bending.** Like solid section, ram-and-press bending of tube is rapid for bends up to about 165° when close tolerances or low distortion are not critical. The minimum center-line bending radius is about 3 times diameter, but 4 to 6 times is preferable (Ref 1).

**Wrinkle Bending.** In this method, wrinkles are made on one side of the tube by heating with a gas torch while applying a compressive load on the tube section. Wrinkling shortens one side and thus results in a bend. The method is used in the field and is applied to heavy-walled steel pipe up

to 650 mm (26 in.) with bend radii of about 2 times diameter (Ref 1).

**Roll extrusion bending** is a method used to create a large-radius bend in large, heavy-walled pipe by internal swaging on one side. Commercial equipment has capacities from 125 to 300 mm (5 to 12 in.) diameters to produce distortion-free bends with radii of about 3 times diameter (Ref 1).

**Hand versus Power Bending.** Depending on the material and workpiece size, the bending methods may be manual or with power machines. Steel tubing as large as 40 mm (1.50 in.) in outside diameter (OD) with a 1.65 mm (0.065 in.) wall thickness can be bent by hand, but the process is slow and repeatability is questionable.

Manual bending is commonly done by a machine for compression or draw bending, and these manual machines operate on the same basic principles as do powered types. Hand bending techniques include simple form tool for bending ductile material like aluminum tubing (Fig. 5) or machines (Fig. 3). Some hand benders use an adjustable friction device, a kind of sliding

brake, to prevent sliding of the tubing. The friction prevents wrinkles and other defects in bending.

The following two examples illustrate several of the factors that must be taken into consideration in selecting either hand bending or power bending to fabricate tubing.

#### Example 1: Hand Bending of a U-Shaped Furniture Part Having Two 90° Bends.

Bending equipment was needed to produce a U-shaped furniture part with two 90° bends from 19 mm ( $\frac{3}{4}$  in.) OD 1010 steel welded tubing with a 1.25 mm (0.049 in.) wall thickness. The two bends were made to a 50 mm (2 in.) radius as measured on the tube centerline. A small amount of flattening was tolerated. Production rate was 500 pieces per month.

Because no great accuracy was needed and because the production volume did not warrant more than a minimum investment, a bending fixture for compression bending by hand was selected, along with tooling to allow for both bends to be made in one setup. If production volume had been larger, a power-driven bender or a bending press might have been selected.

#### Example 2: Power Bending of Machine Tool Hydraulic Lines.

In the production of hydraulic lines for machine tools, from 9.5 and 13 mm ( $\frac{3}{8}$  and  $\frac{1}{2}$  in.) OD steel tubing and from 6.4 mm ( $\frac{1}{4}$  in.) OD copper tubing, hand bending required 6400 man-hours per year for 44,000 bends. A change to power bending reduced the man-hours needed to 450.

## Tools

Tools used for the bending of tubes are similar to those for the bending of bars (see the article "Bending of Bars and Bar Sections" in this Volume). One important difference is that tools for tubes need carefully shaped guide grooves to support the sidewalls and to preserve the cross section during the bend.

**Form blocks**, or bending dies, resemble those for bending of bars. They either rotate or are fixed, depending on the arrangement of the machine in which they are used. One end of the tube is clamped at the end of the groove in the form block, and the tube is bent by being forced around the block and into the groove. For round tubes, the depth of the groove in the form block should be one-half the OD of the tube to provide sufficient sidewall support.

The block becomes the template for holding the shape of the bend. Form blocks can be made of wood, plastic, or hardboard; if they are to be used for an extensive production run, they can be made of tool steel and hardened.

**Clamping blocks** hold the end of the tube to the form block and maintain the holding force necessary to make the bending action effective. Although the groove in the clamping block should be well formed, the finish should not be so fine that the tube will slip. Ordinarily, the as-machined finish is adequate, but sometimes

Fig. 5 Bending of aluminum tube with a bending form

ridges or serrations are machined into the clamp to increase the holding force. Rosin can be applied to the tube to prevent it from slipping in the clamp.

If the clamped area is to be part of the finished piece, care must be taken to prevent scratches or mars. If the clamping groove has to be ground or polished to provide a good surface, the portion of the tube to be clamped will have to be longer to distribute the higher clamping force better. When the clamping length is short, the end of the tube is sometimes plugged to prevent it from deforming from high clamping forces. Table 2 lists typical clamping lengths for bending steel tubing.

**Pressure dies** are used in the draw bending of tubing to press the workpiece into the groove in the form block and to support the outer half of the tube. The most commonly used pressure die is as long as the developed length of the bend plus some allowance for holding, and it does not slide over the tube but travels with it as it moves toward the bend area (see the article "Bending of Bars and Bar Sections" in this Volume). In one face, it has a groove with a depth that is slightly less than one-half the OD of the tube.

A stationary pressure die or even a roller can be used on noncritical work. Either unit has a tube-forming groove machined in its face. Most stationary pressure dies are made of low-carbon steel, which can be case hardened to resist wear. Tool steel such as O1, A2, or D2, hardened to 55 to 60 HRC, or aluminum bronze is commonly used for sliding dies.

In compression bending equipment, where the tube is clamped to a nonrotating form block, a wiper shoe replaces the pressure die. Its relationship to the workpiece is similar to that of the stationary die described previously in that the wiper shoe slides over the workpiece. However, instead of being fixed, the wiper shoe revolves around the stationary form block, progressively pressing the tube into the form block groove. For most applications, the length of the wiper shoe is from three to five times the OD of the tube. The wiper shoe is made of tool steel and hardened to 55 to 60 HRC, or of a bearing bronze.

**Wiper dies** are stationary straight-groove dies (not to be confused with the wiper shoes already described) that are sometimes needed in draw bending to support the tube on the side opposite the pressure die as the tube is about to be drawn into the contour of the form block. Metal that will form the inside of the bend undergoes severe compression that is transmitted back toward the as yet unbent end of the tube, where it could cause wrinkles if not for the support of the wiper die.

The wiper die has a groove that is machined and ground to conform to the tube being bent and to fit the groove and lips of the form block, ending in a featheredge pointing toward the tangent point of the bend and extending to within 3.2 to 13 mm ( $1/8$  to  $1/2$  in.) of the tangent point. Although it is difficult to maintain this distance without deflection, it must be done meticulously if the wiper die is to prevent compression wrinkles.

Wiper dies are machined from AISI 52100 (or L2 tool steel) for low-carbon steel tubing or from aluminum bronze for stainless steel tubing. Wiper dies are never hardened.

**Mandrels**, which are described in detail in the following section of this article, are of three general types—rigid, flexible, and articulated—and are made to support the inside of the tube during bending. Rigid mandrels fit the interior of the tube and are sometimes shaped to conform to the start of the bend. However, because they are rigid, they support the entire circumference of the tube only as far as the point of bending and not beyond the tangent of the bend. Plug mandrels and formed mandrels are included in this category.

Flexible mandrels bend with the tube. They are generally built up of shims or laminae. This type of mandrel is sometimes used with square tubes and box sections where only a few bends are needed. Inserting and removing flexible mandrels is usually difficult. Articulated mandrels include ball mandrels (discussed subsequently) and various other shaped mandrels that are used in much the same way as ball mandrels.

**Loose fillers** such as sand and various low-melting alloys also serve as mandrels for low-production applications.

**Dies** used in press-type bending machines are similar to those described in the article "Bending of Bars and Bar Sections" in this Volume. Dies, including wing dies for bending presses, may have grooves for one to six tubes to be bent in one press stroke.

**Formed rolls** are used in the roll bending of tubes. Grooves corresponding to the outer surfaces of the tubes to be bent are cut or ground into the outer surfaces of the rolls so that they fit the surface of the tube as it is bent. A more complete description of the rolls used in roll bending is available in the article "Three-Roll Forming" in this Volume.

## Bending Tubing with a Mandrel

Mandrels are sometimes used in bending to prevent collapse of the tubing or uncontrolled flattening in the bend. A mandrel can neither correct failure in bending after the failure initiates, nor remove wrinkles.

**Table 2 Typical clamping lengths for bending steel tubing**

Radius of bend centerline	Wall thickness of tube, mm (in.)	Typical length clamped
1 × OD	< 0.89 (0.035)	4–5 × OD
	0.89–1.65 (0.035–0.065)	3–4 × OD
	> 1.65 (0.065)	2–3 × OD
2 × OD	< 0.89 (0.035)	3–4 × OD
	0.89–1.65 (0.035–0.065)	2–3 × OD
	> 1.65 (0.065)	1½–2½ × OD
3 × OD	< 1.65 (0.065)	2–3 × OD
	≥ 1.65 (0.065)	1–2 × OD

OD, outside diameter

Figure 6 shows five types of mandrels used in the bending of tubing. The plug mandrel and the formed mandrel are rigid, but the three other types shown are flexible or jointed to reach farther into the bend.

The largest diameter of the rigid portion of the mandrel should reach a short distance into the bend; the distance that it extends past the tangent straight portion depends on the type of mandrel and the size of the tube and is usually established by trial. If the mandrel extends too far, it can cause a bulge in the bend. Conversely, if the mandrel does not extend far enough, wrinkles may form, or the outer tube surface may flatten in the bend area.

The need for a mandrel depends on the tube and bend ratios. The tube ratio is  $D/t$ , where  $D$  is the OD and  $t$  is the wall thickness. The bend ratio is  $R/D$ , where  $R$  is the radius of bend measured to the centerline.

Table 3 can be used to determine whether a mandrel is needed for bending steel tubing. Figure 7 shows the usual conditions that require the use of a mandrel and what type of a mandrel is needed.

The nomographs given in Fig. 7 are used in two steps to determine if and when a mandrel is required and which specific type will suffice. In nomograph A, the first step is to find the tube ratio and the bend ratio in the left-hand and center scales and to lay a straightedge across them. The zone on the right-hand scale where the straightedge falls shows whether a mandrel is required, and which type. Bends for which  $D/t$  is more than 40 always require a multiball mandrel.

If a multiball mandrel is indicated, step two requires the user to refer to nomograph B in Fig. 7. As before, the tube ratio and the bend ratio are located in the left-hand and center scales and a straightedge is laid across them. The number of balls needed in the multiball mandrel will be indicated on the right-hand scale.

**Fig. 6** Five types of mandrels used in the bending of tubing. Broken vertical lines are points at which bends should be tangential to mandrel centerlines.

**Plug and formed mandrels** are fixed, and the tube is drawn over the tip of the mandrel in forming. This action work hardens the tube so that it resists flattening during bending. Clearance between the mandrel and the inside of the tube should not be more than 20% of the wall thickness. If the mandrel is too tight, the tube is likely to fail in the bend. Mandrels are necessary in tubes other than round in order to avoid distortion of the cross section. The use of plug and formed mandrels is shown in the following two examples.

**Example 3: Use of a Plug Mandrel in Bending Welded Low-Carbon Steel Pipe.** A short 20 mm (3/4 in.) section of thick-walled (2.9 mm, or 0.113 in., thick) welded low-carbon steel pipe with an OD of 27 mm (1.05 in.) was bent 90° to a 50 mm (2 in.) radius. Despite the thick wall, the small bend radius made it necessary to use a plug mandrel to support the pipe against flattening. Other tools used were a form block, a clamp, and a pressure die.

The bending machine was a power-driven rotary draw bender rated for a maximum of 25 mm (1 in.) extra-strong seamless low-carbon

steel pipe (33.40 mm, or 1.315 in., OD by 4.55 mm, or 0.179 in., wall). The bends were made at the rate of 300 per hour.

**Example 4: Bending Oval Tubing with a Formed Mandrel.** Oval tubing measuring 25×110 mm (1×4 3/8 in.) in outside dimensions and with a wall thickness of 1.65 mm (0.065 in.) was bent on edge to make a U-shape with two 90° bends at 230 mm (9 in.) radius. The tubing was welded hot-rolled low-carbon steel. Wrinkles, shear marks, or other visible defects were not permitted.

The bends were made in a draw bender rated for 90 mm (3 1/2 in.) OD by 2.10 mm (0.083 in.) wall thickness steel tubing with 275 MPa (40 ksi) yield strength. This piece, bent with a formed mandrel, form block, clamp, and pressure die, demanded the full rated torque of the machine. The mandrel was lubricated. The bends were made at a rate of 250 per hour.

**Ball mandrels** with one or more balls are used for many bends. During bending, the metal is stretched tightly over the mandrel, making withdrawal difficult. Withdrawal mechanisms are needed. In thin-wall tubing of softer

metals, as the mandrel is withdrawn, it sizes the bend somewhat, smoothing the stretched metal and correcting the shape of the cross section.

The bodies and balls of one-ball mandrels used on most tubing are commonly made of carburized low-carbon steel, hardened, ground, and polished. For the bending of stainless steels, they are made of polished aluminum bronze.

One-ball mandrels used in the bending of tubes up to 32 mm (1 1/4 in.) in OD generally have a body 0.13 to 0.18 mm (0.005 to 0.007 in.) smaller and a ball 0.25 to 0.36 mm (0.010 to 0.014 in.) smaller than the inside diameter of the tube. Square or shaped tubes require a mandrel that fits closer. If the bends are in one plane, the body and the ball of the mandrel can be grooved to clear weld flash or seams. More commonly, a mandrel is made undersize to clear the obstruction. When the workpiece must be bent in several planes, it can be reinserted with the seam in the groove, but it is usually better to specify tubing with a controlled weld flash.

Ball mandrels are often made with several balls, as shown in Fig. 6. The balls or segments are always smaller than the body, and they can be joined by links and pins, ball joints, or steel cable. A linked or jointed mandrel is usually stronger than a comparable mandrel joined by steel cable. The linked mandrel bends in only one plane and is easier to load than one that is less rigid. The ball-jointed mandrel is also in wide use, and it has the advantage of having rotating balls to equalize wear. Ball-jointed ball mandrels are made in many sizes—down to one for tubes as small as 5.64 mm (0.222 in.) in inside diameter. Ball-jointed and steel cable ball mandrels cannot be grooved to clear weld flash and seams because the mandrel segments rotate.

Many multiball mandrels make bends with a centerline radius that equals the outside diameter of the tubing. Ball mandrels can be used on bends that are not possible with formed mandrels.

**Example 5: Multiball versus Formed Mandrel in Forming a U-Shaped Bend.** A U-shape was produced by making two 90° bends in 32 mm (1 1/4 in.) OD welded tubing of low-carbon steel with wall thicknesses of 1.25 and 1.65 mm (0.049 and 0.065 in.). The bend radius for both types of tube was 60 mm (2 3/8 in.). Wrinkles, shear marks, or other visible defects were not permitted.

For the 1.65 mm (0.065 in.) wall thickness tubing, the bend was made with a formed mandrel, which adequately supported tubing of this wall thickness. However, a formed mandrel could not be used for the 1.25 mm (0.049 in.) wall thickness tubing. For the thinner-wall tubing, the *D/t* ratio was so large that it was necessary to use a well-lubricated three-ball mandrel and wiper die. The ball mandrel was required to support the outer wall in the bend area, and the wiper die was required to prevent wrinkling caused by compression in the inner wall of the bend.

The machine used was a draw bender rated for steel tubing with 90 mm (3 1/2 in.) OD, 2.10 mm

Table 3 Minimum centerline radii for bending steel tubing without a mandrel

Fig. 7 Nomographs for determining when a mandrel is needed and the correct type to use. See text for explanation

(0.083 in.) wall, and 275 MPa (40 ksi) yield strength.

If the formed mandrel had been used in bending the 1.25 mm (0.049 in.) wall tube, the tube would have deformed excessively from inadequate support. A formed mandrel would have to be advanced farther into the bend area than is normally done. This would cause a hump and greater thinning of the tube wall where the outside of the bend was stretched over the end of the mandrel. When wall thickness is less than approximately 1.25 mm (0.049 in.), this technique should not be used because there is not enough metal to take the stretch without breaking.

**Clearances** for mandrels vary from 0 (to produce some bends, the mandrel is forced into thin-wall tubing) to 2.4 mm (0.095 in.) or more. The clearance needed depends on stock material, wall thickness, bend radius, and quality of the bend. The better the bend, the more closely the mandrel must fit.

Mandrels are even more necessary in bending nonround tubing than in bending round tubing (see Example 4). Segmented mandrels must be used in almost all bending of square, hexagonal, and octagonal tubing. The number of segments that are needed in the mandrel usually depends on the wall thickness of the tubing.

**The bending of a fragile thin-wall tube** may require the careful use of a multiball mandrel and a wiper die. If the bend is changed to a larger radius or if a stronger or thicker-wall tube is substituted, the mandrel can be changed to a less complicated one, and the wiper die may not be needed. A plug or form mandrel can sometimes be used instead of a multiball mandrel, even when the bend is made to the minimum practical radius.

**Dimensional Accuracy.** Regardless of other conditions, when accuracy is important, the use of a mandrel is mandatory. The following example describes an application that illustrates the degree of accuracy that can be achieved by using a mandrel.

**Example 6: Use of a Plug Mandrel to Hold Close Tolerance on Four Bends.** The tube shown in Fig. 8 was used in a return-line manifold of a high-pressure hydraulic system on a large tractor. The radius of each of the four bends was required to be within  $\pm 1^\circ$ . Overall length was required to be within  $\pm 0.38$  mm ( $\pm 0.015$  in.).

To achieve this degree of accuracy, a considerable amount of tool adjustment was required during each setup. From two to six tubes were bent before acceptable tubes were produced. To produce a lot of 40 tubes,  $2\frac{1}{2}$  man-hours were required, including setup.

Bending was done in a powered draw bender, using a round-end plug mandrel. The mandrel had a drilled hole to deliver a constant flow of lubricant inside the tube during bending. The lubricant was a mixture of lard oil and low-viscosity mineral oil.

**Mandrel Materials.** Most mandrels are made of tool steel (W1, O1, A2, and F1 are typical

selections) and hardened to 55 to 60 HRC. Polished mandrels usually work best, but ground or machine surfaces are satisfactory when slight markings on the inside of the tube is acceptable. Possible surface treatments include chromium plating of any hardened steel and nitriding of tool steels such as A2 and D2.

Although chromium is now subject to environmental regulation, chromium plating has been used to extend the life of some mandrels. Platings were no more than 0.008 to 0.013 mm (0.0003 to 0.0005 in.) thick because thicker platings may flake off. Sometimes platings were renewed for further use. Plated mandrels would be stripped and replated when the plating was worn through at any point.

## Bending Tubing without a Mandrel

It is less expensive to bend tubing without a mandrel. Trial bending is generally necessary to determine which bends can be made. Tubing with thick walls is more likely to be bendable without a mandrel than thin-wall tubing. Bends with large radii are more likely to be formable without a mandrel than those with small radii. Slight bends are more feasible than acute bends. Wide tolerances on permissible flattening make a bend easier to form without a mandrel. Spring-back is greater without a mandrel, but it can be compensated for by overbending or lessened by increasing force on the pressure die.

When bending nickel alloys with no internal support, the dies should be slightly smaller than those used for bending with a mandrel or filler. Bending without use of a mandrel or filler is suitable only for tube and pipe that have a wall thickness greater than 7% of the OD, or for large-radius bends. Within this ratio, nickel alloy tube can be bent through  $180^\circ$  with no mandrel or filler to a minimum mean radius of three times the OD of the tube ( $3D$ ).

## Machines

The machines used in the bending of tubes are essentially the same as those used in the bending of bars. In general, bending machines fall into three categories: rotary benders (stretch, compression, and draw bending), press benders (stretch and compression bending), and roll benders.

**Fig. 8** Manifold tube that was bent to an accuracy of  $\pm 1^\circ$  on each of four bends. Dimensions given in inches

**Powered rotary benders** are commonly used to bend tubing as large as 200 mm (8 in.) in OD. At least one machine can bend tubing as large as 300 mm (12 in.) OD with a 6.5 mm ( $\frac{1}{4}$  in.) wall, and a few special power benders can bend 460 mm (18 in.) pipe.

Boilermakers normally use power benders that can bend 75 mm (3 in.) OD steel tubing with 13 mm ( $\frac{1}{2}$  in.) wall to a centerline radius as small as 75 mm (3 in.). The following example describes the use of rotary benders.

**Example 7: Bending Steel Tubing for Automobile Seat Frames.** Steel tubing with 25 mm (1 in.) OD and 1.24 mm (0.049 in.) wall was bent  $90^\circ$  to make the frame for automobile seats. The inside of the bend was collapsed into a dimple for clearance, but most of the column strength was maintained by holding the shape of the outside of the bend. This was done in part by collapsing the inner wall of the tube over a convex punch instead of a conventional groove. The centerline radius of the  $90^\circ$  bend was 16 mm ( $\frac{5}{8}$  in.). The bends were made two at a time in a fast rotary bender.

**Bending presses** are hydraulic machines that are made especially for bending both bars and tubes, but most often for tubes. The ram of a bending press can be stopped at any point in the stroke. Wing dies and a cushioning device help to wrap the work around the ram die, as shown in Fig. 9. When the ram moves down, it causes the wing dies to pivot by a camming action and to wrap the workpiece around the ram die. The wing dies wipe the work to control the flow of metal; a compression bend is made on each side of the ram die, without wrinkles or distortion.

A bending press can usually make bends much faster than machines that are not made especially for bending. The open design of the press makes possible the bending of complex shapes in one setup. Single bends can be made sequentially, or the press can make several bends simultaneously. Bends can be made to various angles and in various planes. The tube or bar is usually passed through the press in one direction, and the press makes a sequence of bends automatically. The work is held against stops to locate each bend.

When several bends are made in one or more workpieces at each stroke of the press, all bends are in the same plane. Different angles and bend radii can also be made in the same workpiece, and the angles and spacing of bends can be

**Fig. 9** Essential components and mechanics of a bending press

adjusted. One disadvantage of the bending press is that it causes a slight reduction in the thickness of the workpiece at the bend.

Automatic bending presses are used for production bending. Capacities are 26 to 360 kN (3 to 40 tonf) for bends that generally do not exceed 165°. Bends in the same plane should be separated by a distance equal to twice the OD of the tube. Bends in different planes should be separated by a distance equal to at least three times the OD of the tube. If the bent portion is to be joined with another bend into an accurate circle, the length of the straight legs on each end of the bend should be at least twice the OD of the tube. Bends can be made beyond these limits, but at greater cost. Bends are usually made in dies that are slightly tight on the tubes to prevent flattening and wrinkling. Exhaust pipes for automobiles, with bends in various planes, are made in automatic bending presses, as in the following example.

**Example 8: Forming Automobile Exhaust Pipes from 1010 Steel Welded Tubing.** Figure 10 shows an exhaust pipe 210 cm (82 in.) long with bends to bypass the obstructions on the underside of a vehicle. These pipes were made of hot-rolled or cold-rolled 1010 steel welded tubing with 44 mm (1¾ in.) OD and 1.52 mm (0.060 in.) wall. The hardness was 63 to 78 HRB.

Bending was done in an automatic 180 kN (20 tonf) hydraulic bending press, using a punch with a 125 mm (5 in.) centerline radius in the groove and two wing-die shoes. Locating fixtures and a checking fixture (off the press) were also used.

The press made different angles of bend by using turret-mounted stops to control the stroke. The location of the bend was set by backstops at the right side of the press. Counting the plane of the first bend as 0°, the radial position (roll of the tube) for the plane of each bend in turn was located by stops along a bar on the left of the machine. In loading the tubes for the first bend, it was important to keep all weld seams in the same place so that all tubes would bend alike.

The tube was nested in the wing-die shoes for the first bend, and the work was then moved by hand for each of the other bends. All the bends were standard. Tolerances were:

Angles of bend	±0° 15'
Angles of tube ends (all planes)	±0° 30'
Maximum depth of depressions and wrinkles	3.0 mm (0.12 in.)
Linear dimensions	±1.5 mm (±0.06 in.)

All the bends were made cold. The punch was set to clear the work by 13 mm (½ in.) for loading, and the total machine time to make five bends was less than 8 seconds. Production rate was 130 pieces per hour on a 10,000 piece order.

**Press Bending Nickel Alloy Tubing (Ref 2).** Press or ram bending can be used for nickel alloy tubing, although it does not provide close tolerances and is applicable only to large-radius bends. Bends from press bending are limited to 120°. If a smooth bend is desired, the radius of the bend should not be less than six

times the OD of the tube (6D). A filler material should be used for bends of radii less than 6D.

Pressure dies used in press bending should be at least two times longer than the OD of the tube. Press bending with wing dies is used for unfilled, thin-wall, large-diameter tube.

Annealed nickel alloy tubing is not always preferred for press bending. Annealed tubing of low base hardness is not stiff enough to withstand deformation without excessive flattening. Consequently, nickel and nickel-copper alloys are usually press-bent in the stress-relieved temper. Nickel-chromium alloys have higher mechanical properties in the annealed condition than do nickel and nickel-copper alloys and should be press-bent in the annealed temper. Ideally, the choice of temper for a specific bend should be determined from the results of several trial bends.

**Roll benders** for bending tubes are similar to those used for bending bars, as described in the article "Bending of Bars and Bar Sections" in this Volume, but tolerances are more critical on the rolls and spacing. Roll benders are discussed in the article "Three-Roll Forming" in this Volume. The contour of the rolls must match that of the tube to minimize wrinkling or flattening. Tubes of sizes up to 203 mm (8 in.) OD by 6.10 mm (0.240 in.) wall can be bent into arcs, circles, or helices. Rings are easily made on three-roll benders. Helix coiling is described in the following example.

**Example 9: Coiling a Helix of Round Steel Tubing in a Three-Roll Bender.** Steel tubing of 50 mm (2 in.) OD and 6.10 mm (0.240 in.) wall was coiled in a three-roll bender into a helix 610 mm (24 in.) in mean diameter with 65 mm (2½ in.) pitch and 20 turns, as shown in Fig. 11. The tubing, 38.4 m (126 ft) long, was made by welding together random lengths 3.0 to 7.3 m (10 to 24 ft) long. The welds were then ground flush. The form rolls were contoured to fit the 50 mm (2 in.) OD of the tubing. The tubing was started into the rolls so that it coiled without stop until the helix was completed. If the coiling had been stopped, the diameter of the helix might not have been constant. After coiling, the helix was removed and trimmed to length.

Roll bending is the principal method of producing helical coils, spirals, and circular configurations from nickel alloy tubing. Bending may be done on either unfilled or filled tube. The

minimum bend radius that can be attained on unfilled tube is approximately six times the OD of the tube.

## Hot Bending

Most of the bends described so far in this article have been made by cold bending (workpiece at room temperature). There are obvious advantages to cold bending:

- Heating equipment is not needed.
- The benefits of previous heat treatment are not destroyed.
- Subsequent cleaning or descaling is less likely to be needed.
- Workpiece finish is better.
- Thermal distortion is avoided.

On the other hand, cold bending demands more energy than hot bending for the same bend. There is more springback after a cold bend and more residual stress in the tube. Bends cannot be made to as small a radius cold as they can hot.

Tubes are bent hot to make bends of small radius, adjacent bends with little or no straight tube between them, bends in material with little cold ductility, bends that take too much power to bend cold, and bends in fragile assemblies where the force of cold bending might cause damage. Temperatures and procedures in the hot bending of carbon, low-alloy, medium-alloy, and stainless steel tubes are summarized in Table 4. The disadvantages of bending tubes hot include high cost, slow production, and poor finish on bends.

Tubes of carbon steel and most alloy steels can be bent to a much smaller radius by hot bending than by cold bending. A bend radius of 0.7 to 1.5 times the OD of the tube can usually be made by hot bending. The wall thickness of the tube affects this range. The tube wall must not be so thin that it will distort or thin excessively in the outer wall. If the tube ratio (OD divided by wall thickness) is more than 10, the tube probably needs internal support in bending,

**Fig. 10** Automobile exhaust pipe produced in an automatic hydraulic bending press. Dimensions given in inches

**Fig. 11** Coiling a helix from round steel tubing by three-roll bending

unless there is some upsetting of the tube that thickens the wall.

Figure 12 shows the tube-geometry characteristics that can usually be bent hot in a die without a mandrel. Figure 13 shows the tube configurations that can usually be bent hot with a mandrel or filler. Figure 12 applies to tubes 38 to 75 mm (1.5 to 3 in.) in diameter; Fig. 13 is for tubes of all diameters.

If a mandrel is not practical for internal support of the tube, the tube can be packed with dry sand. First, a plate is welded to one end of the tube to block the end. The tube is filled with sand and is tamped or vibrated to make sure the sand is packed tightly. Another plate is welded to the open end, the tube is heated, and the bend is made. Finally, the plates are cut off and the sand is emptied out. Various specialized techniques for bending tubes hot are described in Examples 10, 11, and 12.

**Example 10: Five-Step Bending of a Tube.** Return bends for the coils of a boiler were made by bending 50 mm (2 in.) OD carbon steel tube 180° on a 38 mm (1½ in.) centerline radius.

The tube had a 6.60 mm (0.260 in.) wall. The sequence of operations was:

- Bend 180° on 114 mm (4½ in.) centerline radius in a conventional rotary bender.
- Heat the bend area to 980 to 1095 °C (1800 to 2000 °F) in a furnace.
- Reshape the bend to 50 mm (2 in.) radius in a bending press.
- Close legs to 75 mm (3 in.) between centers in a vertical press.
- Restrike in the vertical press to make bend radius 38 mm (1½ in.).

The last three operations were performed in rapid sequence so that all bends were made before the tube cooled below 870 °C (1600 °F). Production rate was 30 pieces per hour.

**Thinning of the outer wall** can sometimes be controlled better in hot bending by heating only the part of the workpiece that will be the inner wall of the bend. This reduces its compressive strength so that the bend causes very little stretch of the outer wall. This method makes good bends with centerline radii of 1.3 to

1.5 times the OD of the tube with the usual tooling in a rotary bender.

Boiler tubes are bent by heating one side for one-third of the way around the tube. The heated portion becomes the inside of the bend, and because it yields more easily in compression, thinning of the outer wall is limited. The tubes are bent to a U-shape in a bending machine. The U can then be reheated on the inside as before, and the bend can be squeezed in a press in one or more steps to make a narrower U, as in the following example.

**Example 11: Localized Heating for a Compression Bend.** Return bends were made for use in the economizer of a boiler. The tube was made of carbon steel, 50 mm (2 in.) OD by 7.21 mm (0.284 in.) wall. The operations were:

- Heat the tube to 705 to 730 °C (1300 to 1350 °F) in a special burner that heated the bottom 120° of the tube for a 457 mm (18 in.) length where the bend was to be made (Fig. 14).
- Bend the tube in a rotary bender 180° to 190 mm (7½ in.) between centers with the heated portion on the inside of the bend.
- Squeeze the tube between dies in a hydraulic press to 150 mm (6 in.) between centers.
- Squeeze, as in the third step, to 120 mm (4¾ in.) between centers.
- Squeeze, as in the third step, to 90 mm (3½ in.) between centers.
- Reheat the entire surface of the bend for 200 mm (8 in.) on each side.
- Size in a die.
- Squeeze, as in the third step, to 64 mm (2½ in.) between centers.
- Normalize.

The production rate, with three men working, was 20 bends per hour.

**Dry Sand as Filler.** Large tubes are commonly bent hot while they are filled with dry sand. The bending is done on a bending table made of cast iron plates. The plates have a continuous pattern of cored holes. A bending form for the desired radius is bolted to the bending table. Steel pins or stops can be placed in the holes in the table to keep the work in line.

**Table 4** Temperatures and procedures for hot bending of steel tubes

Steel	Temperature, °C (°F)	Procedures
<b>Carbon steels</b>		
ASTM A106, A178, A192, A210	980–1095 (1800–2000) or < 730 (1350)	Do not heat beyond 1095 °C (2000 °F) and do not bend between 730 and 870 °C (1350 and 1600 °F)(a).
<b>Low-alloy steels</b>		
ASTM A209, A213 (grade T11 and T22), A335 (grade P2)	980–1095 (1800–2000) or < 730 (1350)	Do not heat beyond 1095 °C (2000 °F) and do not bend between 730 and 870 °C (1350 and 1600 °F)(a).
<b>Alloy steels</b>		
ASTM A213 (grade T5 and T9)	980–1095 (1800–2000)	Do not heat beyond 1095 °C (2000 °F) and do not bend between 730 and 870 °C (1350 and 1600 °F)(a). Heat treat after bending 730–745 °C (1350–1375 °F).
<b>Stainless steels</b>		
Types 304, 310, 321	> 1150 (2100)	After bending, heat treat to 1095–1120 °C (2000–2050 °F). Furnace cool to 315 °C (600 °F); air cool(b).
Type 446	> 1150 (2100)	Do not bend less than 870 °C (1600 °F). Heat treat at 790–870 °C (1450–1600 °F); water quench.

(a) Ductility is sometimes low in this range; therefore, the range should be avoided for hot bending. (b) This treatment has proved best for maximum strength in service at elevated temperature.

**Fig. 12** Chart for determining conditions for the successful hot bending of tubes 38 to 75 mm (1.5 to 3 in.) in diameter without the use of mandrel

**Fig. 13** Chart for determining conditions for the successful hot bending of tubes of all diameters with the use of a mandrel or filler

**Fig. 14** Compression bend produced in tubing, and special burner used for localized heating of the workpiece before bending. Dimensions given in inches

A clamshell furnace in sections is the usual source of heat. Winches, jacks, and hoists supply the bending force. A typical application is described in the following example.

**Example 12: Hot Bending a Large Tube on a Cast Iron Bending Table.** A 180° bend with a 380 mm (15 in.) radius was made near the center of a 460 cm (15 ft) length of steel tube, 185 mm (7 1/4 in.) OD by 25 mm (1 in.) wall. A plate was welded to one end of the tube to close it. The tube was dropped, closed-end down, into a pit and was filled with sand. The tube was vibrated and tamped to make sure the sand was well compacted, and the open end was closed with another welded-on plate.

The bending table was set up for the bend. The proper form block was bolted to the table, and lines tangential to the bend were laid out for proper location of stop pins (Fig. 15).

The tube was heated to 980 to 1095 °C (1800 to 2000 °F) in a clamshell furnace and set on the bending table. One end was clamped down to the table. The other end was pulled by a cable, which, guided by a series of strategically located pulleys fastened to the table, bent the tube incrementally around the form block to the final position shown in Fig. 15.

When the bend passed inspection, the ends of the tube were cut off and the sand was poured out. The entire process, including preparation and handling, took 45 min.

**Hot Bending of Nickel Alloy Tubing (Ref 2).** When possible, nickel alloy tube and pipe should be formed by cold bending. If hot bending is necessary, it can be performed by standard hot bending methods. Nickel alloy pipe should be cleaned thoroughly prior to heating and bending. The metal should be worked as soon as possible after removal from the furnace to avoid cooling before bending is completed.

Hot bending is normally limited to tube and pipe larger than 2 in. schedule 80 (60.5 mm, or 2.375 in., OD, and 5.54 mm, or 0.218 in., wall thickness). Thin-wall tubing should not be bent hot because it is difficult to retain sufficient heat to make the bend.

**Fig. 15** Final position in the hot bending of a large sand-filled tube

Hot bending should be done on filled tube only. As mentioned previously, sand is a suitable filler material. For nickel alloys, the sand must be free of sulfur because contamination of nickel alloys by sulfur causes cracking during bending. Sulfur can be removed from sand by heating to about 1150 °C (2100 °F) in an oxidizing atmosphere. In addition, the tubing must be thoroughly cleaned prior to filling.

Sand-filled tube and pipe in small sizes (60.2 to 72.9 mm, or 2.37 to 2.87 in., OD) can be bent hot to a minimum mean radius of two times the OD of the tube. Larger sizes require greater bend radii.

Because of the wide variety of nickel alloys and the multitude of uses, alloy producers should be consulted regarding cooling rates for specific alloys after hot forming operations. Improper cooling rates can lead to sensitization to corrosion, lower strength, and reduced ductility.

**Local heating by induction heating** can rapidly heat a specific section of tubing or pipe, which can then be bent. The pipe is clamped at both ends and the circumferential section where the pipe is to be bent is inductively heated. Once the appropriate temperature is attained, the pipe is pushed through the induction coil, and pipe is bent by the action of the bending arm clamped to the front end of the tube. Bends of up to 180° can be made with this arrangement. Bending speeds can range from 13 to 150 mm/minute (0.5 to 0.6 in./minute) (Ref 3–5). If large bend radii are required, bending rolls can be used.

Induction heating is an efficient and cost-effective method of hot bending pipe or tubing. The benefits of using induction heating for hot bending of pipe or tube include (Ref 3–5):

- Reduced power consumption required for heating
- Predictable shape (ovality)
- Minimal and uniform wall thinning across bend
- Little change in surface finish
- Creation of small radii
- Creation of multiradius curves in one tube

**Hot versus Cold Bending.** The selection of hot or cold bending can depend on available equipment, the cost of new equipment, labor costs, the urgency of the job order, and the size of the production lot.

## Tube Stock

Tubes are classed as seamless, welded, lock-seam, butt-seam, and jacketed.

**Steel tubing** is available both seamed and seamless. Seamed tubing with internal flash demands special consideration when a mandrel is to be used in bending (see the section “Bending Tubing with a Mandrel” in this article).

Lock-seam tubing can be bent if the seams are tight. A test is to twist a 914 mm (3 ft) long section of tubing in the hands; any grating or slipping indicates a seam too loose to make good bends.

Butt-seam tubing is similar to welded tubing but with no weld at the joint; it is seldom used. To make good bends, it must be accurate in dimensions, have no scale, and be bent with the seam in the plane of the bend. A mandrel must always be used. It is more economical to use welded tubing.

Stainless steel jacketed tubing is made by roll forming a sheet of stainless steel onto a butt-seam tube of low-carbon steel. The stainless steel jacket is rolled into a lock seam in the open seam of the inner tubing. For best bending, the stainless steel jacket should be at least 0.51 mm (0.020 in.) thick, and the two layers should be rolled tightly together. Tools for bending such jacketed tubing cost more than tools for bending plain tubing; an aluminum bronze wiper die, a hardened steel mandrel, and unusually high pressure on all tools are required, and all of these add to the cost of the tooling. In addition, the seam must be in the plane of the bend, either inside or outside.

Galvanized steel tubing can be bent to a radius as small as four times the OD. For tube to be bent to smaller radii, galvanizing should be done after bending because the galvanized coating is likely to flake if galvanized stock is used.

Aluminum-coated tubing (hot dipped) can be bent by essentially the same techniques used for uncoated tubing of the same diameter and wall thickness, using slightly higher clamping pressures to avoid slipping. Additional information is available in the article “Press Forming of Coated Steel” in this Volume.

Seamless tubing should be free of scale or rust. Wall thickness, concentricity, and hardness vary in seamless steel tubing. These variations are likely to cause variable springback, wrinkles, and excessive flattening. Common pipe in all sizes and thicknesses is easily bent if it is clean and free of rust or scale, inside and out.

**Stainless steel tubing** can be bent to a greater angle, at a given radius, than low-carbon steel. Austenitic types in the 300 series are most commonly bent because they are strong and ductile. Tubing in a stabilized condition at a temper no higher than quarter hard will make good bends with low scrap rates. Both welded and seamless tubing are available. Thin-wall tubes should have the exact diameter and wall thickness specified. Annealing is usually recommended after bending operations.

**Copper alloy tubing** is usually extruded. It is easily bent in the annealed condition, and it has little springback. Copper and some brasses may not need to be annealed. Copper-nickel alloys, however, are more difficult to bend and have greater springback.

When copper alloys are annealed, as most of them are, oxides should be removed by pickling before the tube is bent to protect the tooling. Oxides increase friction and wear in bending.

**Aluminum alloy tubing**, like copper alloy tubing, is usually extruded, or extruded and drawn. Soft aluminum may tear or collapse upon bending. The oxide coating that forms on

exposed surfaces of aluminum alloys is abrasive to tooling. Lubrication prolongs tool life.

Anodized aluminum and decorated aluminum can usually be bent without damaging the finish. Aluminum pipe is bent by hand to a radius usually not less than four times the OD. The bending of aluminum tubing is discussed in the article "Forming of Aluminum Alloys" in this Volume.

**Nickel alloy tubing and pipe** can be formed by all common forming operations. Bending, coiling, and expanding can be performed readily on nickel alloy tube and pipe, using the same type of equipment as is used for other metals. In general, material in the annealed condition is recommended. Alloys 400, 200, and 201 can be formed in the stress-relieved temper; however, the amount of deformation will be limited by the higher tensile strength and lower ductility. In bending, the minimum radius to which stress-relieved tubing can be bent is 25 to 50% greater than it is for annealed tubing of the same size.

The minimum radii to which nickel alloy tubing can be bent by various methods are given in Table 5. Depending on equipment design, tube size, and quality of the finished bend, it is possible to bend to smaller radii than those listed; trial bends should be made to determine whether the smaller radii are practical.

Heat treatment should be considered if cold worked of nickel alloys intended for use at elevated temperatures. Although cold working generally increases strength, it can also increase precipitation rates, reducing corrosion resistance and ductility in materials exposed to elevated temperatures. Consult with materials producers for the appropriate heat treatment after cold formed parts intended for elevated temperature service.

**Draw bending** is the most common bending process and the preferred method for bending nickel alloy tube. The process is similar to compression bending, except that the bending form revolves and the pressure die either remains stationary or slides along a straight line. The sliding pressure die is preferred because it distributes the applied stresses more evenly.

Bends of up to 180° with a minimum radius of 2D can be produced by draw bending. Bending can be done with or without a mandrel. In general, a mandrel is preferred and must be used

when the ratio of tube diameter to wall thickness is above the limit suitable for bending without tube wrinkling or collapsing. Various types of mandrels are used, including ball and plug types.

**Compression bending** uses a stationary bending form and a movable wiper shoe. This method is unsuitable for thin-wall tubing and is generally used with no mandrel support. Compression bending can produce bend radii down to 2.5D but is normally used only for large-radius bends. The maximum included angle that can be produced is 180°.

## Bending Thin-Wall Tubes

The techniques used to bend thin-wall tubes are the same as those used to bend standard tube and pipe, but they are more carefully applied. A tube can be classified as thin wall if the ratio of OD to wall thickness ( $D/t$ ) is greater than 30 to 1. The wall thickness, if not related to the tube diameter, is a meaningless measure. For example, a tube wall 0.51 mm (0.020 in.) thick would be a standard wall thickness for a tube 3.2 mm (1/8 in.) in OD, but for a 152 mm (6 in.) tube it would be a very thin wall. The centerline radii given in Table 6 for bending tubing of various  $D/t$  ratios with a ball mandrel and a wiper die are conservative and are often exceeded.

**Machines** used to bend thin-wall tubing have a greater capacity than necessary so that they will be stable and rigid. Their bending action must be smooth and steady. Runout on machine spindles should not exceed 0.013 mm (0.0005 in.). Mandrel rods must be heavy enough so that they do not stretch or buckle when the slip-fitting mandrel is inserted into the tubing.

Auxiliary equipment includes:

- A means for pressurizing the tubes with air or hydraulic oil (hydrostatic mandrel) to keep them from necking after they are drawn past the last mandrel ball
- Hydraulic feed on pressure dies to hold tubes in compression
- Mandrel oscillators that move the mandrel back and forth to keep the tubes from necking down

The amplitude of mandrel oscillation can be adjusted from 3.2 to 25 mm (1/8 to 1 in.); frequency, from 1 to 500 cpm.

**Tools** for bending thin-wall tubes must be more accurately made than those for standard tubes. The form block or bending die should have a runout at the bottom of the groove of not more than 0.025 mm (0.001 in.). The depth of the groove should equal 55% of the OD of the tube. The width of the groove should equal the OD of the tube plus 10% of the wall thickness. The width of the clamping groove on the bending die should equal the OD of the tube minus 10% of the wall thickness. The length of the clamping groove should be five to six times the OD of the tube, unless special clamping provisions such as flaring or clamping cleats are included. The clamp and the bending die can be keyed or doweled for perfect alignment. Clamping plugs are sometimes used; these should either be slip fitted in the tube or expandable.

The pressure die should have a groove wider than the tube OD by an amount equal to 15% of the wall thickness. The width should not vary from end to end by more than 0.013 mm (0.0005 in.). Variation in the groove will cause a pinching or relieving effect. If all tools are properly adjusted, only light pressure is needed on the pressure die, which can be adjusted against a solid bar with the same diameter as the OD of the tube.

The wiper die has a groove whose width is equal to the OD of the tube plus 10% of the wall thickness. The groove should be highly polished and have a thin coat of light oil. Too much or too heavy oil will cause wrinkles. The groove must be a full half-circle in cross section to support the entire inner half of the tube. The groove must also fit closely to the form die for at least 15° back of the point of bend so that it cannot be forced away by the pressure buildup of the compressed inner wall of the bend. Failure to maintain the position of the wiper die can cause wrinkles.

Multiball mandrels are generally used with thin-wall tubes. They have a clearance no greater than 10% of the wall thickness of the tube. The mandrel must be positioned very carefully so that the full diameter of the body is just at the start

**Table 5 Minimum bend radii for nickel-base alloy tubes**

Bending method	Minimum bend radii	
	Minimum mean bend radius(a)	Maximum included angle of bend, degrees
Press bending, unfilled tube	6D	120
Roll bending, filled tube	4D	360

(a) No wiper die required

of the bend (first ball of cable or ball-socket mandrels at the bend tangent). A template should be used to set the mandrel. If auxiliary oil or air pressure in the tube is not used, there must be enough balls to reach completely around the bend.

Interlock tooling is sometimes used for bending thin-wall tubes. The clamp is keyed to the form block, the wiper die is locked to the pressure die, and the pressure die is locked into alignment with the form block. Interlock tooling was developed specifically for automatic bending, but it has some advantages for general bending. The tools will not crush or mark the work, and setup time and scrap can be reduced.

**Material** should be especially uniform in thin-wall tubing that is to be bent and should all be from the same source—preferably the same heat. Because tooling dimensions are held closely, close-tolerance tubing is recommended despite its added cost.

**Thin-wall tubing of nickel alloys** can be mandrel-bent through 180° to a minimum mean radius of 2D. To minimize galling of the inside surface of the tube, mandrels should be made of hard alloy bronze rather than of steel. If steel mandrels are used, they should be chromium plated to reduce galling (Ref 2).

Mandrels must be lubricated before use; chlorinated oils with extreme-pressure additives are recommended for severe bending. For less severe bending or for ease of removal, water-soluble lubricants can be used.

If a mandrel is not practical, any conventional filler material, such as sand, resin, and low-melting alloys, can be used. Sand is the least desirable because it is difficult to pack tightly and thus can lead to the formation of wrinkles or kinks during bending.

Low-melting alloy fillers produce the best bends. The expansion characteristics of these fillers ensure that voids are eliminated and a sound carrier is created. Alloy fillers are removed by heating the bent tube in steam or hot water. Metallic fillers must not be removed by direct torch heating because they contain elements such as lead, tin, and bismuth that will embrittle nickel alloys at elevated temperatures. All traces of metallic fillers must be removed if the tube is to be subjected to elevated temperatures during subsequent fabrication or during service.

**Production Example.** Thin-wall tubing is frequently bent to elbows that have a centerline radius equal to the diameter, and it is not uncommon for the diameter to be as much as 90 times greater than the wall thickness—for example, a 152 mm (6 in.) diameter tube with a 1.65 mm (0.065 in.) thick wall. Many such elbows are used in vacuum-line service, an application in which no wrinkles are permitted. They are commonly made from 1020 steel tubing in the as-received condition. Bends are made with ball mandrels, wiper dies, and an oil-base lubricant. Some manufacturers of elbows use chromium-plated tools to minimize tool wear.

It is often difficult to prevent thin-wall tubing from slipping during bending. Methods used to

provide adequate clamping are described in the following example.

**Example 13: Procedures to Prevent Slipping of Tubes during Bending.** The tube shown in Fig. 16 was used in a high-pressure hydraulic circuit of an earthmover. Five bends, ranging from approximately 20 to 86°, were made in a powered compression bender. All bends were made on a 152 mm (6 in.) centerline radius.

The 86° bend posed a problem because only 127 mm (5 in.) of tube was available for clamping; adjacent bends were in other planes. Surfaces of the clamps were rough, but the tube slipped during bending, causing unacceptable bends. The first approach was to line the clamps with emery cloth, but this did not add enough friction to prevent slipping. A second approach was to increase the force on the clamp. Until a hydraulic cylinder could be installed to provide this force, a factory lift truck was used. Acceptable bends were produced by increasing the force on the pressure die.

The tubing had a phosphate coating. A three-ball mandrel with an oil hole provided a constant supply of lubricant (a mixture of lard oil and mineral oil) to the inside of the tube. Tools were of W1 or W2 tool steel, hardened.

### Lubrication for Tube Bending

Where a mandrel is used, both the mandrel and the interior of the tube are heavily coated with a thick lubricant. Pigmented lubricants are useful for adding body between the mandrel and the tube. Thick lubricants are sometimes heated to 120 °C (250 °F) and sprayed onto the inner surface of the tube. An oil hole in a mandrel can be used to lubricate the inside of a tube during bending (Example 13).

Fig. 16 Component of a hydraulic system that required five bends. Dimensions given in inches

The wiper die, on the other hand, needs only a very light lubricant, applied sparingly, if at all. Nothing must interfere with the close fit between wiper die and tube, which prevents compression wrinkles.

Not all metals react to lubricants in the same way. In general, mineral oils are always acceptable, as are organic fats. Certain sulfur and chlorine additives can stain or corrode stainless steel or copper and should be used with caution. For aluminum, special additives have been developed for use with light or medium mineral oil; the same formulations work well on copper and brass.

### Tube Forming

Tubular sections are converted into a variety of products. One or more forming processes can be used, including press forming, contour roll forming, tube spinning, rotary swaging, hydraulic bulging, explosive forming, electromagnetic forming, and electrohydraulic forming.

**Press Methods.** Expanding with segmented dies (Fig. 17) is a frequently used method for forming configurations in the sidewalls of drawn shells or sections of tubing. With this method, the forming segments are contracted by compression springs and are expanded radially by a tapered punch. The backup, or outer, die is made of two segments, held apart by compression springs. In operation, as the press ram descends, cams move the two segments of the backup die together. The punch then moves the inner segments outward, forming the shapes in the sidewall. As the press ram is raised, springs return the die parts to their original positions, and the workpiece is rotated 45° for a restrike operation. Restriking is required to remove flat spots resulting from the stretch across the gaps between the forming segments in the expanded position. The size of the gap can be decreased by increasing the number of segments. The presence of the gaps

Fig. 17 Use of segmented dies for expanding a section of tubing in a press

is one of the disadvantages of this method and is the reason that an alternative method, such as rubber-pad forming, is sometimes used (see the article "Rubber-Pad Forming and Hydroforming" in this Volume). The following example describes the forming of a tube section by the rubber-pad method.

**Example 14: Bulging by Rubber-Pad Forming in a Segmented Die.** The hose-coupling tube shown in Fig. 18 was formed by bulging two beads with a rubber punch in a

**Fig. 18** Bulge-formed beads on a coupling tube using a rubber punch in a segmented die

segmented die. The workpiece, with the rubber punch in it, was held in the die on the bed of the press while a closely fitting plunger was lowered into the tube by the upper ram. The compression of the rubber punch caused outward expansion of the tube walls into the two grooves in the die, thus forming the part.

**Nosing of Tubing.** Tubing is often used for making mortar shells by nosing. Shells are machined before instead of after nosing and can be reduced by as much as 30% of their original diameter by nosing.

**Contour roll forming** is used not only to make seam-welded tubing but also to produce a variety of cross sections by reshaping the tubing. This process is discussed in the article "Contour Roll Forming" in this Volume.

**Tube spinning** is an established method for altering the shape of tubing, most commonly to produce a tubular part with two or more wall thicknesses. Tube spinning often precedes some other forming operation.

**Other tube-forming methods** include rotary swaging, hydraulic bulging, explosive forming, and electromagnetic forming. These processes are discussed in numerous articles in this Volume.

**Fig. 19** Steps in the production of a rear-axle housing from a tubular blank. Dimensions given in inches

**Combination Procedures.** A tubular blank can often be effectively used to produce a specific shape by several different operations, which may include piercing, reducing, expanding, and upsetting. The rear-axle housings described in the following example were made in seven steps from tubular blanks. Several types of forming were involved.

**Example 15: Rear-Axle Housing Formed from a Tubular Blank.** The rear-axle housing shown in Fig. 19 was produced from 1035 steel tubing in seven manufacturing operations. The 2020 mm (79 1/2 in.) long tube (Fig. 19a) was first pierced to form the slot (Fig. 19b). Each end was then reduced (at room temperature) from 194 to 132 mm (7 7/8 to 5 3/16 in.) in diameter, as shown in Fig. 19(c). This operation increased total length to 2290 mm (90 1/4 in.) and increased wall thickness in the reduced sections from 7.70 to 9.27 mm (0.303 to 0.365 in.). The workpiece was then heated to approximately 760 °C (1400 °F) in a gas-fired conveyor-type furnace. In the heated condition, the center section of the workpiece was rough formed (Fig. 19d) by means of an expanding bar that was inserted through the slot, rotated 90°, and expanded with a tapered shaft. While the workpiece was still hot, the tapered transition sections were formed by pulling a shaped plug into each throat area.

The circular section was formed by cold rolling (Fig. 19e). At the same time, the flanges were flattened. The flanges were machined, and reinforcing rings were welded on, as shown in Fig. 19(f). The wheel ends were tapered, reduced in diameter, and increased in wall thickness by hot upsetting (Fig. 19f). The housings were machined to locate the brake flanges and the spring pads, which were welded on (Fig. 19g). Other machining followed. The machined housing is shown in Fig. 19(h).

# Straightening of Bars, Shapes, and Long Parts

BARS, bar sections, structural shapes, and long parts are straightened by bending, twisting, or stretching. Deviation from straightness in round bars can be expressed either as camber (deviation from a straight line) or as total indicator reading (TIR) per unit of length. Total indicator reading, which is twice the camber, is measured by rotating a round bar on its axis on rollers or centers and recording the needle travel on a dial gage placed in contact with the bar surface, generally midway between the supports. The indicator reading divided by the distance between the supports gives the straightness in TIR per unit of length. Alternatively, the deviation is expressed in terms of the distance between the supports. The effect that changing the distance between supports has on the reading is illustrated in Fig. 1; the difference in readings illustrates the importance of including support distance and location of indicators in a straightness specification.

Sections other than round are usually checked for camber by placing a straightedge against the bar and measuring with suitable gages the distance between the straightedge and the bar at the midpoint of its length. In flat bars and structural members, camber is sometimes referred to as the deviation from straightness parallel to the width, and bow as the deviation parallel to the thickness (Fig. 2).

Runout is minimal at the nodes of curvature. If a bar has compound curvature, it can be misleading to check for camber or TIR only at the

midpoint of the bar length. Serious errors may result unless dial-gage readings are taken at short intervals over the entire length of the bar, or unless gangs of indicators are used at short intervals along the bar.

**Straightness Tolerances.** Federal Specification 48 ("Tolerances for Steel and Iron Wrought Products") establishes the straightness tolerances on some steels as:

- Hot-rolled carbon steel bars: 6.4 mm deviation per 1.5 m ( $1/4$  in. deviation per 5 ft) or 4.2 mm per m (0.050 in. per ft)
- Hot-rolled alloy steel and high-strength low-alloy steel bars: 3.2 mm deviation per 1.5 m ( $1/8$  in. deviation per 5 ft) or 2.1 mm per m (0.025 in. per ft)
- Hot-rolled stainless steel and heat-resisting steel bars for machining: 3.2 mm deviation per 1.5 m ( $1/8$  in. deviation per 5 ft) but not to exceed 2.1 mm per m (0.025 in. per ft)
- Cold-finished carbon steel bars; turned, ground, and polished bars, or drawn, ground, and polished bars: machine straightened within limits (1.6 mm deviation per 1.5 m, or  $1/16$  in. deviation per 5 ft) reasonable for satisfactory machining in an automatic bar machine
- Cold-finished stainless steel and heat-resistant steel bars for machining: 1.6 mm deviation per 1.5 m ( $1/16$  in. deviation per 5 ft) but not to exceed 1.0 mm per m (0.0125 in. per ft)

- Carbon steel, stainless steel, and heat-resistant steel structural shapes (except wide flange sections): 2.1 mm deviation per m (0.025 in. deviation per ft)
- Wide flange sections used as beams: 1.0 mm deviation per m (0.0125 in. deviation per ft)
- Wide flange sections used as columns: up to 14 m (45 ft) long, 1.0 mm deviation per m (0.0125 in. deviation per ft) but not over 9.5 mm ( $3/8$  in.); over 14 m (45 ft) long, 9.5 mm ( $3/8$  in.) plus 1.0 mm per m (0.0125 in. per ft) beyond the 14 m (45 ft) length

## Material Displacement Straightening

**Manual Straightening.** The original method of hand straightening is still used extensively when accuracy and precision are required or when the shape of the bar or part makes machine straightening impractical. The tools used in manual straightening include hammers and mallets, anvils, surface tables, vises, levers, grooved blocks, grooved rolls, twisting devices, various fixtures, and heating torches. The use of a grooved block (Fig. 3a) illustrates the basic principle of manual straightening by bending.

Shafts for centrifugal irrigation pumps are an example of parts that usually must be manually straightened because of the accuracy required and the necessity of doing the work at the installation site. Most of these shafts are 3.0 to 6.1 m (10 to 20 ft) long, have diameters of 19 to 50 mm ( $3/4$  to 2 in.), and are of cold-drawn 1045 steel. The steel supplier generally straightens the cold-drawn stock within 0.13 or 0.25 mm (0.005 or 0.010 in.) TIR in 3.0 m (10 ft), but the shafts are often bent slightly in transport and in handling. It is common to hand straighten the shafts at installation—within 0.13 mm (0.005 in.) TIR in 6.1 m (20 ft). The shafts are rotated on supports and are deflected with a lever.

Special cold-drawn sections as long as 3.7 m (12 ft) are commonly straightened manually. Many special sections are similar enough to standard flats that they can be straightened in standard two-direction roll straighteners, but quantities are often too small to warrant the cost

Fig. 1 Effect of distance between supports on straightness readings for round bars

Fig. 2 Camber and bow in flat bars

of special rolls. Other special sections may be too complex in shape for machine straightening.

Special sections almost always have twist after cold drawing. The twist must be removed before the section can be straightened. One end of the section is held in a vise or in a special fixture, while the other end is twisted with a wrench or special handle. When the twist is corrected, the bar can be straightened to remove camber and bow.

**Manual Peening.** Straightening of a workpiece by peening (material displacement) is accomplished manually by placing the workpiece on heavy, flat plates and rapidly hammering on the concave side of the distorted portion of the workpiece surface. Elimination of the distortion allows the workpiece to lie flat. This method is applicable when straightening round parts with a high degree of hardness, such as drill bit blanks. Unfortunately, the technique is time consuming and does require highly skilled operators.

**High-Production Peening.** In peen straightening, also known as pulse straightening, the workpiece is pulsed on the low side opposite the

high point of the bend (Fig. 4). The pulsating tooling compresses the workpiece material and burnishes its surface. To counteract existing stresses in the workpiece, the material expands to straighten the part. The metal structure is stabilized, the part retains its straight configuration in storage, and the material is unaffected by the shock and vibration encountered during subsequent machining operations. This method is gaining wide acceptance in high-volume production operations in which cast and forged steel camshafts, hardened steel transmission shafts, crankshafts, and disk plates require straightening.

**Stretch Straightening.** Many bars and shapes can be easily straightened by stretching. However, this technique is usually confined to the straightening of shapes that are uniform in cross section and length. The advantages of stretch straightening include low costs for tooling and for maintenance, simplicity of operation, and (usually) completion of straightening in one operation. The disadvantages include waste by trimming 152 to 467 mm (6 to 18 in.) from the ends of bars damaged by gripping, the need (usually) for two men to do the straightening, the need for cutoff equipment, and production of only 30 to 40 bars per hour.

A stretch straightener has two heads with grips that clamp on the ends of the bar. One head can be adjusted to suit the workpiece length. The other head (tailstock) is powered for stretching and for rotation to correct twist in the workpiece.

Stretching machines are made in sizes to exert stretching forces of 135 to 4450 kN (15 to 500 tonf) to workpieces that may be from 6 to 30 m (20 to 100 ft) long. Stretching must stress the work beyond its yield strength. For complete straightening, the bar should be stretched 2%. To accomplish this and to overcome the greater strength caused by work hardening, the stretching machine needs a capacity of 10 to 15% beyond the yield strength of the bar.

Some straightening can be done by stretching only to the yield strength of the work, but this would not be sufficient to remove completely some sharp bends and twists. A stretcher with a capacity of 1340 kN (150 tonf) can straighten, to some extent, a low-carbon steel bar with a cross section of 9700 mm<sup>2</sup> (15 in.<sup>2</sup>), 6450 mm<sup>2</sup> (10 in.<sup>2</sup>), of austenitic stainless steel, or 4550 mm<sup>2</sup> (7 in.<sup>2</sup>) of ferritic stainless and can do complete straightening on 8400 mm<sup>2</sup> (13 in.<sup>2</sup>) of low-carbon steel, 5150 mm<sup>2</sup> (8 in.<sup>2</sup>) of austenitic stainless, or 3900 mm<sup>2</sup> (6 in.<sup>2</sup>) of ferritic stainless steel. Figure 5 shows the relationship between stretcher force and the cross-sectional area of the bar. The deviation that remains after

stretch straightening can sometimes be corrected by manual straightening.

Most hot-rolled bars can be straightened by stretching. Straightening by stretching also works well on rolled and extruded bars of aluminum and austenitic and ferritic stainless steels, but not on martensitic stainless steels unless they are first annealed. Low-carbon steels are easy to stretch straighten, but annealing before stretching becomes more necessary as the carbon content increases. Because it is slow and limited in effectiveness, stretch straightening is not widely used.

## Straightening by Heating

Alloy steel bars and shapes with a hardness exceeding 50 HRC, as well as fabricated stainless steel parts, frequently warp because of the stress set up during fabrication, machining, or heat treatment. These items can usually be straightened by the application of heat and, in most cases, force. The heat can be localized in the area to be straightened, or the entire piece can be heated—either to the tempering temperature or to about 30 °C (50 °F) below it. (Heating to a temperature above that required for tempering will reduce the hardness, as will prolonged heating at the tempering temperature itself.) Low-carbon steel bars can also be straightened by heating.

**Localized Heating.** Torches are used to apply heat to the convex side of warped parts. A small area is heated to a dull red. The localized heating causes the workpiece to expand, but some straightening occurs during cooling. Skillful heating, cooling, and gaging of the workpiece can result in reasonable straightness.

Torch heating causes soft spots in hardened steel workpieces. Localized heating with a torch can also cause localized residual tensile stress that can be undesirable even in an unhardened workpiece if it is subjected to cyclic loading.

In press straightening with the use of localized heat, the workpiece is supported at each end with

**Fig. 3** Principle of straightening by bending. (a) Manual straightening with a grooved block. (b) Straightening in a press. (c) Simplest form of rotary straightening. (d) Two-roll straightening. (e) Five-roll straightening. (f1 and f2) Two arrangements of rolls for six-roll straightening. (g) Seven-roll straightening. (h) Wire straightening. In all methods shown, the bar is supported at points A and B, and force at C on the convex side causes straightening. See text and subsequent illustrations for details of the straightening methods shown here.

**Fig. 4** Schematic of principles involved in straightening by automatic peening

**Fig. 5** Relationship between stretcher force and area of bar cross section in the stretch straightening of steel bars of various yield strengths

suitable blocks. A stop block is placed directly under the ram to limit the amount of deflection. With the high points of its curvature up, the workpiece is pressed down until it rests lightly on the stop block; heat is then applied. For a heat-treated workpiece, the amount of heat is usually governed by the original tempering temperature, and the distance the workpiece can be deflected and released without fracture depends on the type and hardness of the steel, the heat treatment, and the shape of the workpiece. Another method of controlling deflection without breakage is to place the workpiece on shims while it rests on a flat surface, apply pressure to the surface of the workpiece, then heat and release. If the workpiece is still not straight, it will be necessary to use more shims and reheat or to allow the workpiece to cool longer before releasing the pressure.

Where a flame cannot be effectively directed or may damage the metal, a small weld bead can sometimes be used as the source of heat. Weld beads are applied to the convex area, allowed to cool, and machined off if necessary.

**Heating below Tempering Temperature.** Heating and press straightening are generally not applicable to steel at high hardness levels. The force required to cause permanent set is close to the rupture strength of the steel, and even with extreme care, failure is probable. At medium and lower hardness levels, heating to a temperature about 30 °C (50 °F) below the tempering temperature will permit press straightening to be done successfully. Straightening becomes more difficult as the part cools, and only slight corrective straightening should be attempted at the lower temperature levels. Considerable skill is required to perform such operations and to hold tolerances within 0.08 to 0.25 mm (0.003 to 0.010 in.) over a length of 0.45 to 1.22 m (18 to 48 in.).

After the workpiece has been straightened, it is tempered to the required hardness. Tempering relieves stress set up during straightening and during the hardening cycle. This stress will often deform the workpiece; consequently, workpieces straightened by heating and pressing should be clamped in restraining fixtures during tempering. Fixturing can correct a slight distortion and prevent distortion during tempering.

**Temper straightening** is used to correct the distortion caused by heat treatment. The workpiece is first tempered to a hardness somewhat higher than required, then clamped in a straightening fixture and tempered to the required hardness. The greater the hardness difference between the first and the corrective tempering operations, the more accurate the dimensions will be. Temper straightening is most successful at hardness levels of 55 HRC and lower.

Deep-hardening alloy and tool steels that are being martempered to minimize distortion should be held straight during the cooling period after austenitizing and until the completion of martempering. If straightness is not maintained throughout martempering, the workpiece will warp as martensite continues to form. Straight-

ening should be done below 480 °C (900 °F). Cold bars or chills contacting the high side will more rapidly extract the heat from the workpiece and aid in straightening.

## Straightening in Presses

Round bars up to 50 mm (2 in.) in diameter and from 0.6 to 3.0 m (2 to 10 ft) in length are often straightened in an arbor press. Larger workpieces are similarly straightened in power presses, which may have power rolls and hoists to move the work.

The principle of press straightening is illustrated in Fig. 3(b). The bar to be straightened is supported at points A and B with the convex side of the bow or kink toward point C. Sufficient force is applied at C to cause the bar to become bowed in the opposite direction. The force must be great enough to exceed the elastic limit of the material, but it must set up just enough strain in the bar to allow it to return to the straight position (but no farther) when the pressure is released. The greater the bow in the bar and the higher its elastic limit, the greater the force required to produce the correct amount of strain. To straighten a bar by press straightening, the metal must be capable of cold deformation, and it must strain harden.

In press straightening, the operator usually locates kinks or bows in round bars by holding a piece of chalk close to the surface of the bar and then rotating the bar so that any high spots will be marked by the chalk. The high spot is then brought under the ram of the straightening press, and sufficient force is applied to remove the kink or bow. In shapes other than rounds, the out-of-straight condition must be detected visually or with the aid of a straightedge. This type of straightening requires considerable skill on the part of the operator. A straightening press is sometimes referred to as a gag press and the straightening operation as gaging.

Hydraulic or mechanical presses are used to straighten bars, shapes, and shaftlike parts before, between, and after heat-treating operations. Some bars that are roll straightened do not meet straightness requirements and must receive a final press straightening. Presses are also used to straighten large diameter bars in preparation for turning or grinding. Finish-ground or turned products with highly finished surfaces are press straightened to avoid the spiral marks produced by rotary straightening. Press straightening does not change the size of the bar, but rotary straightening—because of the rolling action or the alteration in residual stress caused by bending or both—may cause a change in bar size.

Some high-strength steels and stainless steels are too hard to be straightened in any way except in a press, and some metals are too hard to be straightened without heat, unless the bar is first annealed. The cold straightening of bars of these metals may cause the bars to break.

Press straightening is easier when the bar has a hardness of less than 40 HRC. The bar can be

retempered to relieve the stress introduced during straightening.

In a straightening press, a round bar is usually set on spring-loaded rollers near the ends of the bar. Thus, the bar can be rotated on its axis while a dial gage shows any deviations from straightness. As the press ram moves down, it presses the bar into V-blocks that support the straightening pressure. This action is repeated, sometimes with the bar shifted or the roller supports moved, until the bar is straight enough to meet specifications. The V-blocks and roller supports can be moved to change the leverage and to adjust the application of the force. A straightening press is better suited to the correction of short bends and kinks than to the correction of long bends. A straightening press can hold the distortion of heat treated bars and shafts to 0.25 mm (0.010 in.) or less, as shown in examples 1 and 2.

**Example 1: Straightening of a Heat Treated Shaft in a Press.** A D2 tool steel shaft with a hardness of 63 to 65 HRC and a straightness specification of 0.25 mm (0.010 in.) TIR is shown in Fig. 6. The shaft was hung in a vertical furnace and preheated to 205 °C (400 °F), 540 °C (1000 °F), and 815 °C (1500 °F) before heating at 540 °C (1000 °F). The part was air cooled to 260 °C (500 °F). Because inspection at that temperature showed distortion of 0.38 to 0.64 mm (0.015 to 0.025 in.) TIR, the bar was straightened in a manual hydraulic press to 0.18 mm (0.007 in.) TIR before it cooled to 205 °C (400 °F). At 65 °C (150 °F), the shaft was again straightened to within 0.18 mm (0.007 in.) TIR.

The shaft was clamped in a V-block for tempering at 150 °C (300 °F) for 6 h, then given a subzero treatment and straightened to within 0.20 mm (0.008 in.) TIR. The shaft was again clamped in the V-block, using shims for straightening, while being retempered at 150 °C (300 °F) for 6 h. Final straightening in the press was to 0.18 mm (0.007 in.) TIR, which was better than was required.

**Example 2: Straightening of a Heat Treated Bar in a Press.** A flat bar of O1 tool steel having

**Fig. 6** Shaft and grooved bar that were press straightened after heat treatment. Shaft hardness: 63 to 65 HRC. Bar hardness: 61 to 63 HRC. Dimensions given in inches

a 19 mm ( $\frac{3}{4}$  in.) deep V-groove along one edge is shown in Fig. 6. The specified hardness was 61 to 63 HRC. The top and sides had to be flat within 0.13 mm (0.005 in.).

The bar was preheated to 595 °C (1100 °F), heated at 805 °C (1480 °F), and marquenched at 190 °C (375 °F). The bar was then clamped in a fixture and cooled to 38 °C (100 °F). Inspection showed 0.15 mm (0.006 in.) maximum variation for the top and side. The bar was reclamped in the fixture and tempered at 150 °C (300 °F) to a hardness of 63 to 64 HRC. The bar was reclamped with shims to straighten it and was retempered at 165 °C (325 °F) to a hardness of 61 to 62 HRC. The bar was then straightened in a press within 0.13 mm (0.005 in.) at the top and side.

**Clamping of Workpiece.** If the workpieces in examples 1 and 2 had been heat treated without being clamped, they would have been free to distort and would have needed more press straightening. The straightening of bars and shafts during transformation and during tempering is more efficient and costs less, and it is sometimes the only way in which straightness specifications can be met. Structural parts for aircraft are commonly straightened by a combination of methods, as shown in examples 3, 4, and 5. Example 6 describes a procedure for heat treating and straightening a long, thin rectangular bar in a press. Round shafts are often straightened before they are ground, as in examples 7 and 8.

Straightening presses are used as accessories to other equipment, such as blooming mills that roll blooms or billets 127 to 178 mm (5 to 7 in.) thick. A 1.8 MN (200 tonf) press with a bed 0.6 by 1.2 m (2 by 4 ft) can straighten such blooms or billets within 6.4 mm per 1.8 m ( $\frac{1}{4}$  in. per 6 ft) in lengths as great as 4.9 m (16 ft) without the use of spacers or shims. Many blooms or billets do not need straightening—for example, if they are to be cut into pieces for forging stock.

Example 6 describes a procedure for heat treating and straightening a long, thin rectangular bar in a press. Round shafts are often straightened before they are ground, as in examples 7 and 8.

**Example 3:** A structural aircraft part called a cap was made from modified 4330 steel bar 4.7 mm ( $\frac{3}{16}$  in.) thick by 1.7 m (66 in.) long

(Fig. 7). The part was channel shaped with one flange removed for a portion of its length to produce an angle section. Holes 3.2 mm ( $\frac{1}{8}$  in.) in diameter were made in both sides of the angle section and in the channel section. Heat treatment consisted of suspending the workpiece by the angle end in a salt bath at 845 °C (1550 °F), quenching in salt at 245 °C (470 °F), and air cooling. After being heat treated, the parts were cleaned and checked for hardness (aim was 46 to 49 HRC). With hardness less than 50 HRC, a subzero treatment was given prior to tempering; with hardness of 50 HRC or harder, the workpiece was clamped in a fixture, tempered at 315 °C (600 °F) for 5 h, and finally air cooled. The workpiece warped about 25 mm in 1.7 m (1 in. in 66 in.) after quenching, and a warp of about 6.4 mm ( $\frac{1}{4}$  in.) remained after fixture tempering. A camber of 6.4 mm ( $\frac{1}{4}$  in.) was easily removed manually, but a workpiece with a camber of more than 6.4 mm ( $\frac{1}{4}$  in.) was retempered in the fixture before straightening. Shape and straightness were checked in a fixture using a 0.51 mm (0.020 in.) feeler gage. After being tempered at 315 °C (600 °F), the workpiece had a hardness of 46 to 49 HRC.

Rotation of about 60° was required to correct for 0.76 mm (0.030 in.) twist. An 89 kN (10 tonf) hydraulic press was used to correct short bends. The workpiece was supported on slotted blocks, placed about 360 mm (14 in.) apart, which gave support to the flanges while pressure was applied. A force of about 13 kN (3000 lbf) deflected the channel section 9.5 to 13 mm ( $\frac{3}{8}$  to  $\frac{1}{2}$  in.) for a camber correction of 3.3 mm/m (0.020 in. per 6 in.). A force of 4.4 to 6.7 kN (1000 to 1500 lbf) on the angle section produced about the same deflection and correction.

Stretching was used to maintain spacing and alignment for the 3.2 mm ( $\frac{1}{8}$  in.) diam holes. Because of the thin sections, the part shrank 0.76 to 1.0 mm (0.030 to 0.040 in.) after quenching in salt at 245 °C (470 °F). To correct this shrinkage, the part was preheated at 290 °C (550 °F) for 30 min, then clamped in the tempering fixture and heated at 315 °C (600 °F) for 5 h. As the fixture expanded from the heat, the part was stretched. After slowly cooling in the fixture, the part had a permanent stretch of 0.51 to 0.76 mm (0.020 to 0.030 in.), which corrected hole

alignment and spacing. About 8 min was required for clamping the part in the tempering fixture, and 22 min for hand straightening.

**Example 4:** A welded double-channel structural member made of 4340 steel 1.8 m (72 in.) long and weighing 5.2 kg (11.5 lb) (Fig. 8) was austenitized at 830 °C (1525 °F) for 40 min, martempered at 245 °C (470 °F), stress relieved at 205 °C (400 °F), and cleaned. The unusual feature of this operation was the simultaneous straightening, bending, and tempering.

The workpiece was machined on a straight plane and then fixture bent 7° on one end during tempering. The fixture was constructed with various gibs and filler blocks milled to fit the contours of the workpiece, including allowance for the 7° bend, which extended for approximately 305 mm (12 in.) (Fig. 8). The workpiece was then placed on the fixture, and all holding clamps were placed in position. The fixture-and-workpiece assembly was then heated to 315 °C (600 °F). At this time, all clamps were tightened, thus making the 7° bend at one end. The assembly was then heated (tempered) to 540 °C (1000 °F) for 4 h.

After tempering the channel was straightened in a hydraulic press to achieve final alignment within 0.76 mm (0.030 in.). A special gage was used to inspect alignment and the bend. Time for straightening and gaging was 30 min.

**Example 5:** A structural bar with a tapered-width channel 4.8 mm ( $\frac{3}{16}$  in.) thick and 1.7 m (66 in.) long was made of 17-4 PH stainless steel (Fig. 9). The part was solution treated to 39 to 42 HRC, finish machined, then aged for 1 h at 480 °C (900 °F). It was straightened to within 0.38 mm (0.015 in.) camber in a hydraulic press upon removal from the aging treatment. The part could be straightened only until it cooled to 370 °C (700 °F), which took 10 min. Because 20 min was required to straighten the part, reheating to 480 °C (900 °F) was necessary.

The channel was supported on two blocks 406 mm (16 in.) apart while force was applied by a pressure ram through a block fitted to the inside contour (upper view, Fig. 9). A force of 13.3 kN (3000 lbf) deflected the part about 25 mm (1 in.) for a correction of 0.51 mm (0.020 in.). Force was applied at 50 mm (2 in.) increments along the bar.

Two 44 kN (5 tonf) hydraulic presses mounted on a large steel table were used to remove the twist. One ram held one end of the part against a block on the table while the second ram untwisted the part (lower view, Fig. 9). A slotted

**Fig. 7** Aircraft part that was straightened by a combination of methods. Hardness: 46 to 49 HRC. Dimensions given in inches

**Fig. 8** Welded structural member that was straightened during and after heat treatment. Dimensions given in inches

bar served as a lever to twist the channel 30° for a permanent correction of 0.83 mm per 1 m (0.020 in. per 24 in.) or 1.3 mm (0.050 in.) for the entire length.

**Example 6: Straightening a Long, Thin Rectangular Bar in a Hydraulic Press.** A rectangular bar of 17-4 PH stainless steel was 75 mm (3 in.) wide, 2.1 m (84 in.) long, and 6.4 mm (1/4 in.) thick (except for 75 mm, or 3 in., at each end, where it was 25 mm, or 1 in., thick). The bar was solution treated and finish machined, which caused a bowing of 6.4 mm (1/4 in.). The bar was clamped in a fixture and aged at 480 °C (900 °F), which reduced the bowing to 3.2 mm (1/8 in.). After aging, the bar was removed from the fixture, reheated to 425 °C (800 °F), and straightened in an 89 kN (10 tonf) hydraulic press, using 13.3 kN (3000 lbf) of force between support blocks 406 mm (16 in.) apart. This caused deflection of 19 mm (3/4 in.) for a correction of 0.76 mm (0.030 in.). It took 20 min and two to three ram strokes per 406 mm (16 in.) setup, as well as five setups per bar, to straighten the bar within 1.5 mm (0.060 in.).

**Example 7:** A shaft of medium-carbon steel, 102 mm (4 in.) in diameter by 6.1 m (20 ft) long, was heat treated to 269 to 321 HB, straightened for turning, turned in a lathe, and then straightened for centerless grinding. The shaft lay on rollers beneath the ram of the press, which permitted it to be rotated and to be moved along its axis. Spring-loaded blocks supported the rollers so that straightening pressure would first deflect the springs, letting the shaft down on movable V-block anvils for straightening. The springs pushed the rollers up, lifting the shaft off the anvils when the ram moved up. The shaft was rotated under a dial indicator to find the high spots. The spots were marked with chalk so that they could be moved beneath the ram. The shaft was straightened within tolerance by pressing, moving the shaft, and pressing again. In an 8 h day, 5 to 15 shafts were straightened.

**Example 8:** After being heated to 1010 °C (1850 °F) and air cooled, a shaft of D2 tool steel, 50 mm (2 in.) in diameter by 1.7 m (66 in.) long,

was straightened within 0.51 mm (0.020 in.). The straightening began when the shaft had cooled to 480 °C (900 °F) from 1010 °C (1850 °F). An 89 kN (10 tonf) hydraulic press applied 8.9 kN (2000 lbf) of force to the shaft, which was supported on anvil blocks 457 mm (18 in.) apart. The shaft was continuously gaged with dial indicators as it was rotated on its axis in order to check the location of the high and low points.

Between 480 and 260 °C (900 and 500 °F), the shaft deflected easily under a load of 910 kg (2000 lb), causing a deflection of 3.2 mm per 508 mm (1/8 in. per 20 in.). When the shaft cooled further, straightening was more difficult and required increased force and a longer holding time.

Gaging and straightening continued until the shaft had cooled to 65 °C (150 °F); the shaft was then tempered at 480 °C (900 °F) for 2 h, resulting in a hardness of 59 to 60 HRC. A difficult shaft was sometimes clamped to a 76 by 76 by 1830 mm (3 by 3 by 72 in.) bar with shims and retempered. If the straightness error was 2.0 mm (0.080 in.), a 1.5 mm (0.060 in.) shim was used on each end for a deflection of 3.5 mm (2.0+1.5 mm), or 0.140 in. (0.060+0.080 in.), and the shaft was retempered at 495 °C (925 °F). The higher tempering temperature made the shaft slightly softer but generally straightened it within the specified 0.51 mm (0.020 in.).

## Parallel-Roll Straightening

Roll straightening is a cold-finishing mill process by which bars and structural shapes are provided with straightness adequate for most applications. For bars and shapes on which close tolerances must be maintained, roll straightening can be followed by press straightening.

In one type of roll straightening, square, flat, hexagonal, and other flat-sided bars are continuously passed between sets of parallel-axis rolls (Fig. 10, 11). Uniform bends are introduced such that the bar is straight when it leaves the rolls. By varying the distance between roll centers and the amount of offset, the degree of

bend can be adjusted according to the section size and yield strength of the metal being straightened.

Round bars can be straightened on parallel-axis roll straighteners, but there is no way to prevent a round workpiece from turning on its axis as it passes through the machine. In rotary straighteners, round bars rotate and advance through the rolls so that the bars are bent uniformly in all planes; the rolls are adjustable so that the bars emerge straightened. Rotary straighteners for round bars usually consist of rolls that can be set at variable angles to each other (see the section "Rotary Straighteners" in this article).

**Parallel-Roll Straighteners.** Square, flat, hexagonal, and other flat-sided bars can be straightened in both directions in one pass through a straightener having two sets of parallel rolls in planes 90° to each other (Fig. 10), or in two passes through a straightener having a set of parallel rolls in only one plane, by turning the bar 90° on its axis between passes.

In machines with a single straightening plane, the rolls are mounted on horizontal shafts as shown in unit 2 of Fig. 10. If the horizontal rolls are grooved (like the vertical rolls of unit 1, Fig. 10), the straightening in one plane also produces some straightening in a plane 90° to the first plane.

For high accuracy of straightness and high production rate, a second unit is added in a plane perpendicular to the first unit (Fig. 10). Unit 1 has vertical shafts for straightening curvature in the horizontal plane; unit 2 has horizontal shafts for straightening curvature in the vertical plane. The two driven rolls rotate but are otherwise stationary; the three idler rolls are adjustable away from and toward the workpiece.

**Fig. 10** Arrangement of vertical-shaft and horizontal-shaft rolls in a roll straightener for straightening a rectangular-section bar

**Fig. 11** Straightening of a hexagonal bar in a two-plane roll straightener

**Fig. 9** Setups for straightening and removing twist from a stepped channel. Dimensions given in inches

The first driven roll contacted by the bar is set with enough space between the first two idler rolls to curve the bar uniformly with the concavity toward the first driven roll. As the bar passes over the second idler roll and is held in position by the second driven roll, the concave side of the bar is reversed. The amount of reversal can be controlled by the position of the second idler roll, and with that roll properly positioned, the bar will emerge straight from the third idler roll. With a greater number of rolls, the most severe curvatures are reduced at the entry end of the machine. This results in less work for the remaining rolls and provides for better straightening of small curvatures. The number of rolls in a set of straightening rolls ranges from 4 to as many as 13; the most common number is eight or nine.

The amount of adjustment in roll spacing is determined by:

- The resistance of the work metal to deflection beyond its elastic limit. The greater the resistance, the farther apart the rolls must be spaced to provide sufficient shaft and bearing capacities.
- The distance must be short enough to produce a permanent set in the smallest bar and to straighten it.
- If sections with high width-to-thickness ratios are being straightened, the distance must be great enough so that pressure from the rolls does not upset the edges of the bar.

Machines are built with both fixed and adjustable roll-center distances. In adjustable center distance machines, a separate housing carries the roll assembly to permit positioning along the straightener bed. These housings either reduce the space for the shafts or limit the minimum distance between the rolls.

Most sections can be straightened adequately in two planes. A flat bar is shown in Fig. 10 as it passes between grooved straightening rolls on vertical shafts and then through plain-face rolls on horizontal shafts. The bar passes first through the vertical-shaft unit because it is natural for the bar to enter with the flat side lying against the feed table. It is also natural to straighten in the

grooved rolls first because the grooves that guide the bar also produce some straightening in the second plane and ensure proper entry of the bar into the second unit. If the machine were reversed, it would be desirable to groove the rolls on the horizontal shafts to make certain that the bar would not “walk off” the rolls.

Grooving the rolls for thin flat bars helps to reduce upsetting of the edge and twisting of the bar. A hexagonal bar is shown in Fig. 11 as it passes between grooved straightening rolls on vertical shafts and through flat-face rolls on horizontal shafts. This roll arrangement follows the same principles as those for flat bars.

Sections that are symmetrical in both planes are easier to roll straighten than nonsymmetrical sections. Sections that are symmetrical in one plane but nonsymmetrical in the plane at 90° are usually best straightened in the symmetrical plane. Axial adjustment of some of the rolls to produce additional straightening in the non-symmetrical plane is necessary in this method, as in the straightening of the angle section shown in Fig. 12.

Angles are best straightened in horizontal-shaft rolls with the apex of the angle up and roll adjustment made in the vertical plane. The angle lies naturally on the feed table and is straightened in both directions. To take out bends 90° to the plane in which the angle is straightened, one or two top rolls are adjusted axially to deflect the angle in this direction.

A structural channel can be passed through horizontal-shaft rolls with the flanges of the channel up or down. The upper rolls are staggered vertically and horizontally to remove camber in both planes.

Square or nearly square bars can be straightened on the diagonal in a single-plane machine using V-shaped upper and lower rolls (Fig. 13a) similar to the upper rolls used for straightening the angle shown in Fig. 12. In this method of straightening, only the shaded portion of the cross section shown in Fig. 13(b) is stressed beyond the elastic limit; therefore, the results may not be satisfactory. A square is better straightened in a two-plane machine, in which the areas stressed beyond the elastic limit are greater and more nearly symmetrical, as shown

in Fig. 13(c). Square and hexagonal bars as large as 102 mm (4 in.) and flat bars as wide as 305 mm (12 in.) are straightened in roll straighteners. Larger bars are usually straightened in presses.

Bars of low-carbon steel seldom change size in straightening. Steel having 0.30% C or more may enlarge slightly in section because straightening redistributes the stress that remains from previous operations. For example, a bar of 1045 steel 30 mm (1<sup>3</sup>/<sub>16</sub> in.) square may enlarge 0.05 mm (0.002 in.) in one pass through a roll straightener, and 0.10 mm (0.004 in.) in two passes. The bars shorten as they enlarge in section in accordance with the Poisson's ratio of the material.

Square, hexagonal, and flat bars to 19 mm (3/4 in.) in cross section are sometimes cold drawn from coils of hot-rolled stock. The drawn bars are straightened in roll straighteners and sheared to length. To correct the curvature resulting from coiling, rotary or two-plane straighteners with sets of six to eight rolls in each plane are used.

## Rotary Straighteners

Round bars or shaftlike parts of all types of metal are straightened in rotary straightening machines of two basic types: crossed-axis-roll machines and rotary-arbor machines. The basic principle of rotary straightening is that the workpiece is fed forward and deflected beyond its elastic limit by crossed-axis rolls that also impart the rotary motion. The surface of the bar is alternately subjected to tensile and compressive stresses as it rotates in the straightener. Rotary straighteners are available with two to nine rolls.

A **two-roll rotary straightener** consists of two rolls that are directly opposed and positively driven. One of the rolls is concave, and the other has a relatively straight face (Fig. 14). The angularity adjustment of the rolls at opposite inclinations rotates and feeds the bar through the machine. Straightening is accomplished by flexing the workpiece into the throat of the concave roll by the modified straight-face roll (Fig. 3d). The bar is positioned vertically by means of a bottom guide or top and bottom guides (not shown in Fig. 14) so that the axis of the bar coincides with the centerline of its path between the rolls.

**Fig. 12** Roll straightening of a structural angle. The top rolls can be adjusted horizontally and vertically.

**Fig. 13** Roll straightening of square bars. (a) Setup for single-plane roll straightening. (b) and (c) Stress patterns that result from single-plane and two-plane straightening

**Fig. 14** Arrangement of rolls in a two-roll rotary straightener (top and bottom guides not shown)

The amount of bend given a bar as it passes through the machine depends on two adjustments made by the operator:

- The angle of the rolls to the axis of the bar
- The roll pressure, which is selected by adjusting one of the rolls toward or away from the other

Roll-angle and pressure adjustments depend on the size of the bar being straightened and its mechanical properties. In general, the larger the bar, the greater the roll angle, provided the mechanical properties are about the same. A heat treated bar (tensile strength: 862 to 1030 MPa, or 125 to 150 ksi) will require a smaller roll angle and more pressure than a bar of the same size and grade that has been annealed, or annealed and cold drawn.

In two-roll rotary straightening, the workpiece is subjected to a continuous straightening action from the point of entrance to the work rolls to the end of the workpiece as it leaves the rolls. Therefore, there is no variation in size within the bar, as is sometimes encountered with multiroll straighteners. Two-roll straighteners can be used for short workpieces, such as rocker-arm shafts and chain-link pins, because all of the flexing is contained within the cavity of one roll. Two-roll straighteners are also used for sizing or for correcting out-of-roundness in hot-rolled bars. Extremely soft metal may be reduced in diameter if too much pressure or too large a roll angle is used. Two-roll straighteners can be used to remove end kinks and to round out squashed ends, both of which sometimes occur when bars are cold sheared to length prior to straightening.

Two-roll rotary straighteners inherently have a lower through speed than do multiroll straighteners. The roll inclination must be kept lower (about 20°) in two-roll straighteners; therefore, the rotational speed of the bar is much higher in relationship to the forward speed.

The span over which bending takes place is considerably shorter in two-roll machines than in multiroll rotary straighteners because in two-roll machines, all bending takes place within the length of the rolls and not from roll to roll. With such a short span, much more force must be applied to the bar by the bending equipment than with multiroll machines. Bars from 1.6 to 255 mm (1/16 to 10 in.) in diameter can be straightened in two-roll rotary machines.

In addition to finish straightening, the two-roll rotary machine can be used to rough straighten hot-rolled round bars, which may be very crooked and may have sharp hooks and round and scaly surfaces; to straighten and size cold-drawn round bars, which may be bowed but have no sharp bends; and to polish or burnish to improve surface finish after grinding. Additional rolls should be kept for straightening only, sizing only, and polishing only.

**Multiroll Rotary Straighteners.** Another type of machine used in the straightening of bars is the multiroll rotary straightener. Figure 15 shows a five-roll rotary straightener, which consists of two driven rolls and three idler rolls.

The two end idlers oppose the driven rolls, and between them is the middle or pressure roll. All rolls are concave, and the roll inclination is adjustable in order to obtain the maximum length of contact between the roll surface and the workpiece (see also Fig. 3e). Bottom cast iron guide shoes are located at the entry and exit ends between the driven rolls and their respective opposing idlers to position the bar properly.

A six-roll rotary straightener has a roll arrangement similar to that of a five-roll machine; the sixth roll is placed either opposite the middle roll or outboard of the exit-end powered rolls (see these roll arrangements in Fig. 3f). Seven-roll arrangements consist of two three-roll clusters with a middle idler roll (Fig. 3g). Small cluster-roll straighteners have been used extensively for specialty work on small workpieces, such as valve push rods (~7.9 mm, or 5/16 in., in diam) and rocker-arm shafts; however, these straighteners are used most often for straightening large tubing (60 to 610 mm, or 2 3/8 to 24 in., in diameter).

In operation, the rolls are adjusted angularly to accommodate various bar sizes. With the average angle selected as 30°, the adjustment may vary from approximately 28 to 30°, depending on the size of the bar being straightened.

In a five-roll straightener, the middle idler roll is adjusted to put enough bend in the bar to exceed the elastic limit of the metal. As the bar is fed through the straightener and rotated by the entrance and exit rolls, the adjustment of the pressure roll causes the bar to bend beyond its elastic limit in all directions perpendicular to its longitudinal axis. This action produces a straight bar with symmetrical stresses.

Optimum settings of roll angle vary somewhat with bar size. Typical settings are given in Table 1.

Cold-drawn bars that are straightened in a multiroll rotary straightener usually increase in diameter during the straightening operation. Low-carbon steel bars with up to about 0.15% C show a negligible increase in diameter. However, as the carbon content increases, the amount of change increases. It is not uncommon for 50 mm (2 in.) diameter cold-drawn bars of 1050 steel to increase as much as 0.1 mm (0.004 in.) in diameter. These bars will decrease in length by approximately 13 mm per 3.7 m (1/2 in. per 12 ft) as a result of the increase in diameter. This shortening must be considered when bars are cut to exact lengths before straightening.

When cold-drawn bars are to be straightened in a multiroll rotary straightener, selection of the cold-drawing die size is important if the bars are to be held within standard size tolerances. Most

**Fig. 15** Arrangement of rolls in a five-roll rotary straightener

grades, particularly those having high carbon content, should be drawn to the low side of the diameter tolerance to compensate for the increase during straightening. The extreme ends of the bars, which do not get the full effect of the bend by the pressure roll, do not increase in diameter. After straightening, the bar ends will remain the same size as when cold drawn.

Straightening in a multiroll rotary straightener does not work harden the bar stock to any appreciable extent. This is desirable when the bars are to be cold headed or cold extruded.

The basic five-roll straightener has been modified so that four of the rolls are driven and only the middle pressure roll is an idler. The heavier feeding pressure obtainable with driven entry and exit pressure rolls is advantageous in that a polishing effect can be obtained on products such as cold-drawn steel. In addition, the driven rolls provide more traction so that a heavier deflection can be exerted by the middle straightening roll.

In a further modification of the five-roll straightener, all five rolls are driven. This eliminates the need for guides between the rolls, but roll speed synchronization becomes important.

Hot-rolled round steel bars are generally straightened commercially in two-roll or multiroll rotary straighteners. Bars as large as 255 mm (10 in.) in diameter and having yield strengths up to 690 MPa (100 ksi) have been straightened in these machines. Some machines are modified by adding hydraulic loading to the straightening mechanisms and by adding a shear pin to provide for any shock loading that might be encountered because of the extreme out-of-roundness of large hot-finished bars.

**Rotary-arbor straighteners** are used to straighten coiled rod or wire up to 32 mm (1 1/4 in.) in diameter. The straightening is done by an arbor rotating around the wire as it passes through the machine, as shown in Fig. 16 (see also Fig. 3h). The arbor encloses five pairs of cast iron straightening dies. The dies are equally

**Table 1** Typical settings of roll angle for five-roll rotary straighteners for use on bars of various diameters

Diameter of bar		Setting of roll angle, degree
mm	in.	
19	3/4	26 5/8
25	1	26 7/8
32	1 1/4	27
38	1 1/2	27 1/4
44	1 3/4	27 1/2
50	2	27 3/4
57	2 1/4	28
64	2 1/2	28 1/4
70	2 3/4	28 1/2
75	3	28 3/4
83	3 1/4	29
89	3 1/2	29 1/4
95	3 3/4	29 1/2
102	4	29 5/8
108	4 1/4	29 7/8
114	4 1/2	30

Recommended settings for the starting setup; these will vary slightly in the actual setup used.

spaced in a fixed spacing that relates to the size capacity of the machine. The greater the capacity, the greater the fixed spacing of the dies will be.

The dies, bell-mouthed for easier entrance of the wire, are locked in place by adjusting screws. The pairs of dies at the two ends of the straightener arbor are set so that the wire is always at the center of the arbor in these dies. The middle die is called the pressure die because it is set to bend the wire slightly, as shown in Fig. 16. The dies on either side bend the wire slightly in the opposite direction.

The machine is set by trial. If the wire comes out bowed, usually the pressure die has not been set to bend the wire enough. If the wire comes out wavy, the pressure die may be bending the wire too far. Helical marks may be caused by lack of lubrication, imperfect dies, or an embedded sliver of metal.

**Growth.** During straightening in a rotary-arbor machine, most grades of cold-drawn carbon steel and of alloy steel with more than 0.15% C will increase in diameter (as much as 0.15 mm, or 0.006 in.) unless the wire has been stress relieved before straightening.

**Speed** of straightening in rotary-arbor straighteners is usually 23 to 61 m (75 to 200 ft) per min, depending on the size capacity of the machine and on the type of wire.

**Cut lengths** of bars are straightened in mechanisms such as the one shown in Fig. 17. A helical motion is imparted to the bars by pairs of rotating, offset friction disks, which burnish the bar as they feed it through three straightening bushings that turn freely in bearings. The middle bushing is adjusted to deflect the bar, just enough for good straightening action. Such a machine made in various size capacities can straighten

**Fig. 16** Arrangement of rolls and dies in a rotary-arbor straightener used for the straightening of coiled rod or wire

**Fig. 17** Plane and side views of a mechanism for straightening cut lengths of bars

bars 2 to 32 mm ( $5/64$  to  $1\frac{1}{4}$  in.) in diameter at speeds of 28 to 50 m (92 to 164 ft) per min.

**Straightening Stainless Steel for Cold Heading.** Coiled stainless steel wire (series 300 and 400) 1.6 to 15.5 mm (0.062 to 0.610 in.) in diameter requires moderate straightness while being fed into cold-heading machines. Wire 1.0 to 3.2 mm (0.040 to 0.125 in.) in diameter can be hand straightened sufficiently for entering the feed rolls. The feed rolls then pull the wire with enough tension to remove the coil radius as the wire leaves the coil reel. For parts having a length-to-diameter ratio of 4 to 1 to 8 to 1, no further straightening is necessary. The feed rolls provide sufficient straightness to permit the blank to be cut to length and transferred to the die station. After cold heading, the part has the straightness obtained in the heading operation.

Parts up to 152 mm (6 in.) long cold headed in open-die headers require a straightness of 0.1 mm in 102 mm (0.004 in. in 4 in.). A single-plane five- or six-roll straightener placed 90° to the feed roll is usually used. Single-plane and two-plane straighteners mounted on portable pedestals are available as machine accessories.

### Automatic Press Roll Straightening

One of the fastest straightening processes available is the automatic press roll-straightening method. It is capable of straightening small concentric parts at up to 1200 pieces per hour; larger parts with greater ovality, such as cold extrusion axles and transmission shafts, can be made at 225 pieces per hour.

Roll straightening features support and straightening roll assemblies that resemble those used in a roller V-block, but it includes a headstock unit equipped with a drive mechanism to rotate the workpiece. This process uses a press frame with a hydraulically powered ram (Fig. 18). Two or more lower support roll assemblies are mounted on the bed of the device, while one or more upper support rolls are mounted on the ram. Additional roll assemblies are needed to straighten a series of bows (known as snaking). The headstock consists of a chuck or driver used to rotate the workpiece. The equipment is particularly suited to the straightening of cylindrical solid parts as well as tubular parts

**Fig. 18** Illustration of equipment used in automatic press roll straightening

having walls that are thick enough to withstand the pressure of the rolls without being deformed (see the article "Straightening of Tubing" in this Volume).

The process is initiated by placing the workpiece on the lower rolls and having the driver move forward to engage the part and to rotate the workpiece. The overhead rolls situated on the ram are then applied to deflect the part in a bowlike arc while the workpiece rotates. This procedure subjects the material to a plastic strain. When the material exceeds the yield point, the ram action is released to complete the cycle.

The advantages of this method include a stretch-relieving action that accompanies the straightening as well as the ability to handle a wide range of types and degrees of out-of-straightness conditions. Concentric parts with no ovality can be held to a close tolerance and require minimal operator skill.

The disadvantages of this technique are that it cannot be used on nonround parts, thin-wall tubes, or parts having variable diameters. Only hardened shafts with a hardness of 38 HRC or less should be straightened using this method because the depth of hardness limits its effectiveness.

### Moving-Insert Straightening

Designed for use on linear, flat, or irregularly shaped parts, moving-insert straightening is accomplished by reciprocal strokes transmitted to tooling inserts by a rotary-cam action. When positioned between two rows of movable inserts situated on a tool base, a part is subjected to a series of reciprocal strokes that overbend the workpiece by a preset amount (Fig. 19). The amplitude of the movement is progressively reduced during the cycle until it approaches a straight line, at which point the workpiece is also straight. The degree of bending movement and

**Fig. 19** Moving-insert straightening for linear, flat, or irregularly shaped objects

the number of bending cycles are adjustable, and varying insert spacing is available to accommodate a wide range of soft or heat treated components. The primary advantages of this straightening technique are its ability to straighten flat or irregularly shaped parts, with or without projections, bends, and so on; the ability to produce straightness or slight curves when needed; a tolerance as close as 0.03 mm (0.001 in.) throughout the length of the part, depending on its configuration; and minimal skill requirements imposed on the operator.

## Parallel-Rail Straightening

Parts that feature multiple diameters and heads, such as bolts and spindles, require a straightening device that adjusts to the contours of the workpiece. The parallel-rail method performs this function by employing a series of parallel rails. One group of rails is located on a slide, and the other group is located on a ram or head above and between the bottom rails. As shown in Fig. 20, the cylindrical or thick-wall tubular part is positioned between the rails, and the ram is lowered by adjustable hydraulic pressure to overbend the workpiece. Simultaneously, the lower slide moves forward and rotates the workpiece. At the end of the stroke cycle, the pressure decreases to zero, and the part is now straightened. The configuration of the workpiece determines the number and position of the adjustable rails needed to complete the straightening operation.

With this technique, production rates of 500 to 600 pieces per hour can be obtained with manual loading and unloading methods. Production rates of 1000 pieces or more per hour can be obtained with automatic loading and unloading equipment.

Among the advantages of parallel-rail straightening are:

- Minimal operator skill required
- Easy adjustment to make rails conform to workpiece configuration
- Complex parts featuring headed areas and multiple diameters can be straightened
- High production rates combined with low tooling costs

The primary disadvantage of parallel-rail straightening is that workpiece dimensions are limited by the machine width of 610 mm (24 in.) as well as maximum diameters of 20 mm (0.8 in.).

## Epicyclic Straightening

Epicyclic straightening is suited specifically to straightening linear parts, tubing, and solid cylindrical parts featuring a variety of cross-sectional shapes. After the workpiece is securely supported by locating fixtures at either end, a straightening arm secures the part in the approximate center of its length (additional

straightening arms may be necessary on some parts due to length and configuration considerations). The straightening arm is programmed to move in a circular or elliptical path about the neutral axis of the part. The cross section of the part is taken through its elastic limit as the amplitude of the arm motion is increased. At the elastic limit, the motion decreases, and the arm moves to a stationary position at the neutral axis of the workpiece to produce a straight and stable part.

The motion of the straightening arm is a circular path for round parts, while parts with varying cross sections, such as an I-beam section, require an elliptical path (Fig. 21). The feed rate should be maximized to reach the yield point as quickly as possible. The degree of straightness required determines the feed rate necessary to return the part to its neutral axis.

Epicyclic straightening can be used on such parts as I-beam axles, trailer axles, asymmetrical forgings, and thin-wall propeller shaft or drive

Fig. 20 Parallel-rail straightening for cylindrical or thick-wall tubular parts, either symmetrical or with variations in diameter

Fig. 21 Circular and elliptical paths of the motion arm on an epicyclic straightener. (a) Displacement circular. (b) Displacement elliptical. Ratio  $x:y = 2:1$ . (c) Feed to central axis circular. (d) Feed to central axis elliptical. Ratio  $x:y = 2:1$

shaft tubes. Production rates range from 80 parts per hour (trailer axles) to 300 parts per hour (propeller shaft tubes).

## Straightening in Bar Production (Ref 1)

**Coil Straightening on Spinner Type Machine.** One way coil is straightened is on a spinner type machine having a rotary spinner with generally five dies or more that are offset. The spinner rotates around the bar as the bar is driven through the machine by driven feed rolls. The material from the spinner dies is normally somewhat bright with a condition of straightness that is acceptable to the trade if done properly with tolerances of 0.3 to 0.55 mm/m (0.004 to 0.005 in. per foot) total indicator reading (TIR) as a minimum achievement without special care and operator attention. The reduction in scrap here is the proper size machine for the grade of material to be run. Drawn material from a spinner type machine may be marginal because the material is either at the large or the small end of the range of the machine. If the material resists being straightened, roping (twisted material looking like a rope) can occur. The roping can be very severe; even after centerless grinding there may be low or high spots resembling a wire rope braid.

To reduce scrap from the coil as described it is necessary to use the proper size machine. If a machine has a range of 6 to 19 mm ( $\frac{1}{4}$  to  $\frac{3}{4}$  in.), then the smallest and largest material, as it varies from a mild-steel center state, should be reduced in diameter. For example, a mild steel machine with a 6 to 19 mm ( $\frac{1}{4}$  to  $\frac{3}{4}$  in.) overall diameter would be reduced to 9 to 16 mm ( $\frac{3}{8}$  to  $\frac{5}{8}$  in.) when used with titanium, 1045 steel, or stainless material. This will assure that there is a much better chance of scrap reduction in a rotary center type of machine. There are also variables that can be used between the throughput of a machine and the feed of the spinner. Too high a spinner speed with too slow a throughput speed on extremely difficult to straighten materials on either end of the range of the machine produce roping or, even worse, surface defects. Scrap reduction method, therefore, is to use the optimum speeds and feeds. The selection of the spinner dies is quite important so they are compatible with the material to be straightened. Die materials can range from cast iron through hardened grades of the bronze alloys, stainless and the exotics. The total surface of the coiled material being straightened is contacted by these spinner dies and lubrication is necessary. It is still possible with good lubrication and proper die to get scratches from an improper spinner setting. As the carbon increases in this coiled stock, it is difficult for the spinner to remove all of the stress that is in the coil after it has been drawn through the die around the bull block drum. If the material is 1045 steel or thereabout, a well-straightened scrap-free product must have these stresses completely relieved.

Spinner die type machines are frequently followed by two roll straighteners, either operating in connection with them or off to the side as recovery machines. These machines will remove the wire roping and have the ability, through the action of the concave and straight rolls on the bar, which are restrained by the upper and lower guides, to slow the material to relieve the stresses. Material above 0.30 wt% carbon must be expanded on to be straightened properly, 0.30 wt% carbon about the same; material below 0.30 wt% carbon is compressed when straightened and can lose size. This is an example of one straightening process overcoming the difficulties of another straightening process and recovering what would possibly be scrap or marginal product.

**Straightening Coils from Continuous Drawing Machines.** Another method of producing material from coils is to use a continuous drawing machine. This has a distinct advantage over the coil to coil followed by the spinner type of straightening. The material is in the same coil form but the continuous drawing machine uses reciprocating, nonmarking, gripping guides. The material is drawn through a die in a straight line. Then the material, when cut off, goes to a straightening machine automatically. Unfortunately, the normal straightening machine furnished with the continuous drawing machine is limited to straightness of approximately 0.5 mm TIR/m (0.006 in. TIR/ft). This straightening machine has a series of rotating nozzles—generally five, sometimes as low as three, sometimes as many as seven—and the material is spun up by two attrition disks on either side of these nozzles. The nozzles are then offset, which produces the straightening. The major cause of scrap from straightening by this process is there cannot be a complete end-to-end straightening operation because of the fixed distance between the nozzles. There is generally a scrap problem with the ends of the bars as they are twisted and scarred in the attrition disks. For this reason, they generally are sold in lengths of  $+13$  mm ( $\frac{1}{2}$  in.).

The surface finish from this type of nozzle straightener is generally bright but does have a pattern of loose particles caused by the attrition wheels, and they cling to the bar. The scrap reduction in this straightening is to carefully select the range of materials to be run in the continuous draw machine with only the nozzle type straightener. After passing 30 carbon, this straightening method becomes somewhat erratic and the scrap does go up, especially if trying to maintain a TIR rating of less than 0.5 mm/m (0.006 in./ft).

Again, the scrap reduction method is to put a two-roll straightening machine inline or offline through which to run all or a select group of bars. A direct inline machine eliminates the straightening problems that are attendant with hooked ends that occur in either the shearing and/or the gripping of the continuous drawn machine. The ends of the bars are, for all practical purposes, perfect, having only a 1.6 mm ( $\frac{1}{16}$  in.) or, at the

most, 3 mm ( $\frac{1}{8}$  in.) slight roll down due to the rotational speed. The higher carbon bars are then straightened as precisely as the lower carbon bars because of the ability of the two-roll machine to exert such straightening forces as blow the bars up in diameter by stress relief.

Nonetheless, a continuous draw machine can have an inherent drawback with this operation. It can draw material so fast that a heavy draft (e.g., a  $\frac{1}{8}$  in. reduction in 1 in.) will produce a phenomena that causes erratic straightening at higher speeds, and as the severity of the reduction drops off, the phenomena also disappears. Also, the hooks and bends in the incoming coil of material play an important part in the final straightness. Scrap reduction starts with the incoming material and the method of straightening it prior to the drawing, even going back further to handling the coils so they do not become battered or have wild loops. The addition of a two-roll continuous straightening machine to a continuous drawing line provides a method of scrap reduction in that the material can now be produced to tolerances of 0.15 mm TIR/m (0.002 in. TIR/ft) and less on certain materials, or an average of 0.25 mm TIR/m (0.003 in. TIR/ft) on most materials. The surface finish, while not as bright as that on the attrition wheel, actually is smoother because of the burnishing action of the concave and straight rolls of the two-roll machine, and there are less metal particles on the surface.

Guide scratching in the straightening line is reduced to a very low level with a heavy flow of coolant and the use of the proper grade of guide material, such as cast iron or bronze. Also, an excellent means of scrap reduction is an addition to the two-roll straightening machine of a digital readout that reads the position of the straight roll, i.e., distance, down to 0.25 mm (0.001 in.). The operator then sets the preload, that is, the amount of load on the two rolls, by reducing the opening between the rolls. Customarily, the higher the carbon, the more preload, the lower the carbon, the less preload there will be. For example, if 1045 steel is being run and it is in the 25 mm (1 in.) diameter range with the normal draft of 1.5 mm (0.060 in.), the preload may be only 1 mm (0.040 in.) less than the diameter of the bar. However, if this is increased to a draft of 2 mm (0.090 in.), then the preload might go up to 1.5 mm (0.060 in.). Scrap reduction, therefore, involves the proper use of instrumentation on the straightening machine to inform the operator that the straightening conditions are optimal. It is also exceedingly important that the operator be trained in the proper preparation of the grip jaws as the action of the two-roll machine will provide a very nice polished background; an improperly ground jaw will emboss the surface of the bar and be easily visible normally as four almost continuous lines.

**The straightening of round bars coming from a draw bench** uses the same principles as coil drawing. However, the setup of the two-roll straightening machine, which is always used in

this process, is less severe for a given diameter than the same size from a coil. The product of the fixed draw line straightener tends to have higher yields and less scrap than that from a coil. There are certain economic factors that rule out the production of material on a fixed length draw bench when it can be made from coil at much higher speeds. The operation on larger sizes of material is just as important, and scrap reduction by the two-roll straightener saves a significant amount of material because the weight per foot increases. A slight imperfection caused by the straightening machine process on the surface of an 80 mm ( $3\frac{1}{2}$  in.) bar is far more costly than it would be to a 20 mm ( $\frac{3}{4}$  in.) bar. Again, the straightening machine scrap reduction program starts back at the draw bench, or even before the draw bench. Overblasting or lining can cause difficulties in straightening if they are severe enough. However, most of the difficulty is surface finish. The biggest detriment to the scrap-reduction program in the straightening of drawn bars of fixed length is the proper setup of the drawing die. The drawing die affects not only the size of the bar but also the curvature. The dies

should be universally adjustable by means of four bolts in the corners, operating on a spherical surface to cant the die one way or another. The second or third bar being drawn should be as straight as possible. The scrap reduction from the straightener is then an easy matter because the straightener is not required to overstraighten the product and therefore can straighten every bar.

In the draw line, the shear is important, and especially in that the shear blades be set close enough to give a good cut without a lip. Many a bar is poorly straightened, and scrap results because a bad shear is used or an improper setting that puts a lip on the end of the bar. The operator then cannot feed the lip into the straightener properly and therefore is obliged to misset the straightener to get the lip through. Scrap reduction in the straightening machine is dependent on the improvement of the shear cut and proper straightener setup. The shear table is another scrap producer if it does not drop with the shear blade in the same articulated motion; a hooked end under the shear blade occurs. A good holddown is required to do the same action on the

incoming bars. Often, bars that are improperly straightened can be traced to bad hooks that are produced by the shears.

The proper feed and handling equipment on the input side of the machine with the proper entry device, as well as the proper handling equipment on the exit side of the machine, is required to restrain the bar from high rotation. This almost automatically occurs in the inline drawing but is often neglected in the drawing of bars from a draw bench.

Improperly set up input or discharge tables will cause straightening scrap. Scrap reduction in the straightening of this material requires not only proper drawing but also proper setup of the input table, straightening machine, and the proper discharge table.

# Straightening of Tubing

TUBING of any cross-sectional shape can be straightened by using equipment and techniques that are basically the same as those discussed in the article "Straightening of Bars, Shapes, and Long Parts" in this Volume. In general, a round tube that has warped in annealing or other heat treatment is given a rough-straightening pass in a press or a roll straightener, followed by one or more passes in a rotary straightener and, if required, a finish pass in a press straightener.

Rough straightening eliminates excessive bow that would cause whipping in the inlet trough. Because the tube does not rotate during rough straightening, almost any amount of bow can be accepted; therefore, both roll and press straightening can be used. If the tube is only slightly bowed, initial rough straightening can be omitted.

A rotary straightening pass is necessary for finish straightening but need not be used when the tube requires another cold drawing operation. Two or more rotary passes may be required when the tube has developed excessive out-of-roundness, bow, or multiple kinks in previous processing.

If the tube is considerably out-of-round, a normal straightening pass, with only a middle roll offset, will not be effective. A preliminary pass with no offset in the middle rolls and all rolls set to ovalize may be required before the normal straightening pass.

Most tubing, especially the smaller sizes (32 mm, or 1¼ in., in outside diameter and smaller), requires only one or two rotary straightening passes. For larger-diameter tubing (38 mm, or 1½ in., in outside diameter and larger), or when straightness better than standard is required, additional work can be done in a press straightener to remove short end hooks or to secure precision straightness. Press straightening converts long, gentle bows into a series of short bows ending at each point where the punch hits.

Straightening of tubing having shapes other than round is done in roll or press straighteners with much the same considerations governing the choice as those for similar solid shapes. Asymmetrical sections, such as airfoil or tear-drop designs, require press straightening. Stretch straighteners are helpful in detwisting and straightening asymmetrical shapes.

## Effect of Tubing Material

Procedures and tooling are influenced by the tubing material. The principal factors are the composition and condition of the work metal, wall thickness, type of tubing (seamless or welded), and type and extent of distortion. Greater force and more rugged equipment are required for straightening tubes with thick walls and high elastic limit.

**Wall Thickness.** The amount of distortion that occurs in the hollow section where it bears against the straightening tools is relatively small in thick-wall tubes, which approach solids in their behavior. Distortion becomes significant as tube walls become thinner, necessitating precautions against permanent distortion. Damage to thin-wall tubing appears as spot dinges or ovality from punch straightening, or as spiral dinges (called rings) or ovality from rotary straightening.

**Type of Tubing.** Seamless tubes often have a nonuniform wall thickness, which makes the straightening operations more difficult. In a welded tube, the weld and adjacent material may have mechanical properties that differ considerably from those of the rest of the tube. Residual stress from welding may also affect straightening.

**Type and Extent of Distortion.** Crookedness in tubing can result from distortion during heat treatment or cooling, from distortion during cold drawing as the result of eccentric wall, from hooked ends on hot-finished tubes (usually caused by misalignment or roll wear in the hot sinking mill), or from accidental bending during processing. End hooks are pronounced bends that appear close (usually within 455 mm, or 18 in.) to the leading or trailing ends of some tubular products.

## Control of Straightening Pressure

Pressure exerted on the workpiece by the straightening rolls must be carefully controlled to prevent permanent damage, especially to thin-wall tubing. This can be done by increasing the distance between the points at which the tool contacts the workpiece, thus reducing the total force, or by increasing the contact area between

tool and tubing, thus reducing the unit pressure on the workpiece.

In the rotary straightening of thin-wall tubing, the length of contact between the roll and the tube and the distance between sets of rolls should both be maximum, and care should be exercised in the adjustment of opposed rolls to avoid excessive ovalizing and pressure on a short section of tubing. In a two-roll machine, the length of curve is limited to the length of the roll, and tubing with very thin walls may be subject to ringing at the roll shoulders where the pressure is greatest. This limits the two-roll machine to a maximum diameter-to-wall thickness ratio of approximately 15 to 1 for full straightening.

## Press Straightening

The straightening press can rough straighten tubing prior to roll straightening or rotary straightening, or it can completely straighten tubing by removing end hooks that cannot be removed easily by any other method. End hooks and large cambers sometimes must be removed to permit the tubing to enter the rotary straightener and to prevent dangerous whipping of the work. A press can also be used to straighten welded tubing before the bead is reduced. It is best to reduce the bead before straightening the welded tubing in a rotary straightener.

**Tooling.** In the press straightening of thin-wall tubing, there should be a wide spacing between saddles. If there are short kinks in the tube, the spacing is dictated by their length, and operator skill must be relied on to obtain the best possible straightening.

Rolls with a semicircular groove for holding the tubing are sometimes used for end supports. The spacing of these rolls can easily be adjusted to suit the length of the bow. The pressure shoe attached to the press ram is flat, with a semicircular groove to distribute force over a greater area. The diameter of the groove should approximate the diameter of the tube to avoid flattening of the tube under pressure.

**Applications.** Straightening presses are used on tubes to remove kinks, camber, and other distortions caused by mishandling, cutting off, and heat treatment. Straightening presses can also be used to reduce the out-of-roundness of tubing.

## Parallel-Roll Straightening

Single-plane and two-plane roll straighteners for tubular products are basically the same as those for solid bars. Machines for tubular products may have somewhat longer center distances than bar straighteners and at the same time may not require shafts and bearings that are as large. The roll-center distance is generally a function of the outside dimensions of the tube, and it increases approximately as the outside dimensions of the tube increase. Less force is required for straightening tubes than solid bars of equal outside dimensions.

**Round tubing** is best straightened on machines equipped with semicircular grooved rolls. The grooves must conform closely to the tube size, and each size must have its own set of rolls, or set of grooves in a multigrooved roll. Round tubing will twist slightly in the rolls, thus avoiding the effect of straightening and resulting only in rough straightening.

Tubing that is badly warped can be rough straightened as easily in a roll straightener as in a press. The roll straightener operates faster than the press but takes longer to set up. When straightening 50 mm (2 in.) diameter, 6 m (20 ft) long tubes, for example, the roll straightener can process 250 to 400 pieces per hour as compared to 100 to 120 pieces per hour in a press. However, changeover time for a roll straightener is 16 min; a press setup can be changed in as little as 6 min.

The cost of roll straightening increases greatly for the larger tube sizes. Therefore, a large tonnage of tubes must be processed to justify the cost of machines for straightening tubes that are larger in outside diameter than approximately 75 mm (3 in.).

**Square and rectangular tubing** is commonly straightened in either single-plane or two-plane machines (see the article "Straightening of Bars, Shapes, and Long Parts" in this Volume). If the rolls of a single-plane machine are grooved to fit the tube, an appreciable straightening effect in a plane spaced at 90° is provided. When additional straightening is required, square tubes are turned 90° for a second pass through the rolls. A two-plane roll straightener is better suited to rectangular tubing than a single-plane roller because the rolls need not be reset for the second pass.

## Two-Roll Rotary Straightening

The principle employed in the rotary straightening of round tubes is basically the same as that for solid round bars. The driven rolls, set at a predetermined angle, rotate the tube while conveying it in a lineal direction. The crest of the bow is stressed to, or beyond, the elastic limit once during each revolution, and the maximum stress point is repeated spirally along the length of the tube. The distance between each stress point depends on the lineal travel for each

revolution of the tube. Approximate values for lineal travel can be determined by multiplying the tube circumference by the tangent of the angle of the rolls. Special contoured rolls can be used to eliminate stress points, yielding tubes with uniform stresses.

Two-roll rotary straighteners (see the article "Straightening of Bars, Shapes, and Long Parts" in this Volume) are used primarily on tubes having a diameter-to-wall thickness ratio of no more than 15 to 1. The machine is equipped with two skewed rolls, between which two guide shoes are mounted. One roll has a concave contour; the other is straight or convex. The rolls can be arranged in a horizontal or a vertical plane. Machines with rolls arranged in the vertical plane are of relatively new design.

The tube is held between the guide shoes while the straight or convex roll bends the tube between the ends of the concave roll. The maximum deflection depends on the depth and the skew angle of the concave roll.

Two concave rolls have also been used to straighten tubes. The concave rolls are set to make full-length contact along the surface of the tube, and the crest of the bow is ovalized between the rolls several times before the tube emerges from the machine.

**Straightening of End Hooks.** The two-roll machine can remove most of the sharp bend at the end of tubing if the rolls are ground to suit the deflection requirements of the tube material and are set at an angle to suit the size of tube and length of end hook. The resulting curve in the rolls is suitable for a specific range of tube sizes with a specific elastic limit. Wider variations in tube size and grade of material can be processed by changing the angle setting of one or both rolls to produce the required deflection.

The design of the two-roll machine permits the rolls to be set at a small angle with the centerline of the stock. The smaller the angle, the less through feed per revolution of the tube, and because of the small helix angle created by feed per revolution, a large portion of the tube is subject to maximum bending stress.

Short bends and end hooks can be straightened in a two-roll machine, because all bending takes place within the length of the rolls and not from roll to roll, as is the case with multiple-roll machines. The short span greatly increases the load necessary for straightening, which partly explains why a two-roll machine is unsuccessful in straightening thin-wall tubing.

**Roll Angle.** Contoured rolls are designed for a specific range of tube sizes and materials. This is approximately the same range of conditions that can be handled by the equivalent multiple-roll straighteners. For most applications, the rolls are set at an angle of 15 to 25°. The contour of the rolls can be varied to suit specific applications. For example, a roll of shallow concavity is used for materials having low elastic limits, while a roll of deeper concavity can be used to straighten materials having higher elastic limits.

**Limitations.** The two-roll machine is not ordinarily used to finish straighten tubing if the

ratio of outside diameter to wall thickness is greater than 15 to 1. The crushing strength of a thin-wall tube in the short span of a two-roll straightener is such that the tube will crush, or ring, before it bends if the rolls are set to remove the maximum bend. However, if the amount of bend to be removed is reduced by a preliminary rough-straightening operation, the machine can be used to finish straighten tubing having a diameter-to-wall thickness ratio considerably greater than 15 to 1, depending on the amount of straightening done in the preliminary operation.

Polishing of the tube surface can be either beneficial or detrimental. The hourglass shape of the rolls presents different diameters to the surface of the tube, resulting in some slipping. This burnishing action improves surface finish, although excessive slipping can produce a burnished spiral on the work surface.

Scratches may result when foreign material becomes embedded in the guide shoes. The use of nylon shoes and a soluble oil as a lubricant will reduce scratches.

**Sizing after Derodding.** Producers of cold, drawn tubing use internal mandrels to control the inside diameter, and two-roll crossed-axis machines are used to extract the mandrel (derod) after the drawing process. The identical rolls apply heavy pressure on the workpiece, thus expanding the tubing to allow removal of the mandrel.

The expanded tubing does not always return to its drawn diameter. The external dimensions of tubing can be corrected by drawing the tubing through dies that are undersize by an amount equal to the amount by which the tubing expands during derodding.

## Multiple-Roll Rotary Straightening

Rotary straighteners with five, six, seven, or even more rolls are also used to straighten tubing. The five-roll machine consists of two two-roll clusters and a middle deflecting roll. This machine has two large rolls on one side that are opposed or nearly opposed by three small rolls on the other. Two of the three small rolls and the two large rolls function as entry and exit feed rolls. The third small roll located between the other two small rolls functions as a deflecting roll. The rolls can be arranged in the horizontal or in the vertical plane.

In some machines, only the two large rolls are driven; in others, all rolls except the deflecting roll are driven, and sometimes all five rolls are driven. When more than two rolls are driven, the speed matching of roll surfaces becomes important. Matching can be obtained by maintaining the correct relationship between roll diameters or, more easily and accurately, by a differential drive between the two roll banks or, in some machines, by driving the rolls with individual motors having relay, continuous-feedback, or similar controls.

The six-roll machine has two middle deflecting rolls opposed to one another, similar to the

entry and exit rolls in the five-roll straightener, but it differs from the five-roll straightener in that all rolls are of equal diameter. Normally, four or all six of the rolls are powered. Another type of six-roll straightener has a roll arrangement similar to that of a five-roll straightener with an additional outboard roll.

A seven-roll rotary straightener has two three-roll clusters—one at the entry end and one at the exit end of the straightener—and a middle deflecting roll (Fig. 1). Normally, the two bottom rolls are driven and the five others are idlers. The middle roll (deflecting roll) moves vertically, and the four end idler rolls move in a circular path about pivot points in the base and apply pressure to the tube for feeding and straightening. This seven-roll arrangement has the greatest effect at the middle roll because the tube is held perfectly in the pass.

Various other multiple-roll straighteners have been built for specific applications. The general principles that apply to the use of multiple-roll machines are the same as those already described for two-roll straighteners.

**Middle-roll offset straightening** bends a straight tube by an amount that stresses the outer fibers of the tube to the elastic limit. When the straightening load is released, the tube springs back to its initially straight position. The outer fibers of an initially bowed tube are stressed beyond the elastic limit, and the tube springs back to a straight position.

Straightening of tubing in this manner can be termed single-pass straightening. It is possible, however, to arrange the rolls in the multiple-roll machine to double straighten each tube as it is conveyed through the machine. The middle roll stand is offset to deflect a bowed tube and to stress its outer fibers beyond the yield point, and in a similar manner, the tube is deflected over the third roll stand by an auxiliary roll or by the discharge table. The tube is stressed at both the middle and third roll stands—or, in effect, double straightened—with each pass through the machine.

Bending the tube, however, creates an area of strain or cold work directly under the bending load. The rotation of the tube as it goes through the machine generates a spiral of strained area around the periphery of the tube. The centerline

of the third roll stand should be spaced such that no one point on the tube duplicates itself at the same location on both the middle and third rolls, thus eliminating the possibility of reworking the strained area.

**Tube Deflection.** The amount,  $\delta$ , by which the middle roll or rolls must be offset from the entry and delivery rolls varies inversely with the outside diameter of the tube to be processed, as demonstrated by the following equation:

$$\delta = S l^2 / 6 E D$$

where  $S$  is the yield strength of the metal,  $l$  is the distance between the outboard rolls,  $E$  is the modulus of elasticity, and  $D$  is the outside diameter of the tube.

As the diameter of the tube decreases, the deflection requirements increase over a given span. Therefore, the factor that determines the smallest-diameter tube that a machine can process is the deflection requirement of the tube over the span of the rolls. Approximately 19 mm ( $3/4$  in.) is the maximum deflection that can be applied to most tubes without adversely affecting travel of the tube through the rolls of a rotary straightening machine.

**Applications.** Multiple-roll machines are advantageous in processing thin-wall tubes, and thick-wall tubes having a high ratio of diameter-to-wall thickness. This is because of the lower unit loading on the workpiece that is applied across the longer bending spans between adjacent rolls. The multiple-roll straightener has an additional advantage in higher throughput speeds than other rotary straighteners, because of the higher angularity settings of the rolls. Therefore, multiple-roll straighteners are widely used in tube mill production lines.

Multiple-roll machines are ordinarily used for applications in which the primary purpose is the sizing or burnishing of the workpiece. They do not straighten as accurately as two-roll machines, nor do they remove end hooks effectively.

Long bows in medium- and heavy-wall tubes are removed by closing each roll pass and bending the tube with the middle roll. Closed-pass rolling provides full-length support within each roll stand. Straightening in this manner requires less deflection and spreads the bending load over the full length of each roll.

Long bows can sometimes be removed from extra-heavy-wall tubes by opening each roll stand and bending the tube between the two bottom rolls with the top middle roll. The object is to exert a minimum load on the tube.

Thin-wall tubes should be processed with low unit loads applied to the surface of the tube and with minimum deflection. High loads and excessive deflection will ring the interior of the tube. The bending load can be spread across the surface of the tube by angling the middle roll toward the centerline of the pass. Ovalizing and spreading the roll contact lower the required amount of deflection to produce a straight tube. Deflecting a tube over a long span requires a large offset that can make it difficult to convey

the tube through the machine. However, proper roll design and roll spacing make it possible to process a wide range of outside diameters in the multiple-roll rotary straightening machine.

**End hook** can be removed from thin- and medium-wall tubes by ovalizing and bending the tube in the middle roll pass. Removing end hook from thick-wall tubing on multiple-roll straighteners is difficult because the center-to-center distance between the No. 1 and 2 roll stands is usually greater than the length of the end hook.

**The roll angle** of a straightening machine depends on the outside diameter of the tube to be straightened. In general, a machine used for small-diameter tubing in the range of 6.4 to 19 mm ( $1/4$  to  $3/4$  in.) may have a roll angle of 40 to 45°. In some special high-speed straighteners, when the tubing is almost straight to begin with and is easy to straighten, a 40° angle can be used for tubing as large as 50 mm (2 in.). For machines in the range of 50 to 152 mm (2 to 6 in.), a common angle is 30°. For very large tubing 455 to 610 mm (18 to 24 in.) in diameter, the angle can be as low as 17½°.

To fit a large tube within the size range of the machine to the roll contour, the angle between the centerline of the tube and the roll must be greater than that required for a small-diameter tube. The angle can be adjusted from 2 to 3° on either side of the nominal angle for a given machine—the lowest angle for the smallest size and the largest angle for the largest size.

**Entry and Delivery Tables.** Well-designed entry and delivery tables are important in the rotary straightening of tubular products. The rotary straightening machine is designed to support, guide, and straighten a tube within the length between the first and last roll stands. It is not designed to feed, support, or confine a long tube over its full length.

Entry-table guides confine the portion of the tube that is beyond the limits controlled by the rotary straightening machine in order to minimize rotary whipping of the unstraightened portion. The table guides must be designed to suit the size range, grade of material, and travel rate of tube that is to be processed. A combination of entry and delivery tables and guides keeps the amount of straightener deflection, or offset, to a minimum, increases the range of sizes that can be straightened in any one machine, and decreases the possibility of damaging the tube.

The entry table should also feed the tube into the rotary straightener with skewed rolls, so that the tube will be rotating and moving lineally when it enters the straightener. When in-line straighteners are used at the mill, the straightener and tables must be designed to keep up with the speed of the mill.

## Ovalizing in Rotary Straighteners

Some straightening effect can be produced in certain tubular products not only by bending but also by squeezing them elastically between the

**Fig. 1** Arrangement and principles of operation of three-roll clusters in a seven-roll rotary straightener

opposed straightening rolls as the tubes are processed through a rotary straightening machine. The rolls have a concave curvature through which a line of contact is produced between the roll and the workpiece for almost the full length of the roll.

Machines having sets of two opposed rolls are used to combine bending and ovalizing in the straightening of round tubes. Squeezing results in high residual stresses that can be removed by subsequent bending operations.

**Collapse Strength.** The cold working of a tubular product by bending and ovalizing in a rotary straightening machine can reduce the collapse strength or external-pressure resistance of the tube. Therefore, cold working should be kept to a minimum. The least amount of bending and/or ovalizing that will still yield a straight tube should be used. It is believed that a round tube obtained by squeezing will result in good collapse resistance.

### Straightening in Tube Production (Ref 1)

The simple rule for scrap reduction due to straightness in the tubing industry is to use the proper straightening machine. The range of tolerances of 0.8 mm of total indicator reading (TIR) per meter (0.010 in. TIR/ft) and above can be handled by the normal multicycle, five-, six-, or seven-roll rotary straightening machine. The machine, because it does not have any restriction to the path of the tube, cannot achieve greater tolerances than this unless the incoming material itself is almost to these tolerances prior to being

straightened, and thus, the scrap reduction in the straightener is not normally great because of the loose tolerances.

However, anytime a tube has a ratio of thickness to diameter of less than 30 to 1 and required tolerances better than commercial, a two-roll type of machine is used. The scrap reduction method is to treat this type of tubing as though it were a precision-drawn solid bar. The same comments concerning the ends can be attributed to the method of cutoff. The same tolerances can be lost if the tube is not held against rotation, which would cause it to throw itself out of straightness before going into the straightener, and surface condition on the tube is generally, except for the food-handling type of tubing, important but not necessarily bright.

One interesting example is a machine that straightens tapered golf shafts. When the straightening machine is able to straighten a multidiameter drawn shaft, it is an important cost savings, because it eliminates hand straightening. The material to be straightened has to fit within certain categories, and the diameter of the small end to the large end is approximately a 2.5 to 1 ratio. Precise electronic controls are used to set the machine for each diameter.

The reduction in scrap in some of the drawn-with-mandrel tubing operations is unique. After drawing the mandrel with the tube, it is passed through the standard two-roll straightening machine. The mandrel, being a harder material, is unaffected, and the tube is expanded due to deflection in the straightening machine. The deflection is caused by the straight roll pressing the tube against the concave roll to a measured amount, as indicated by the digital readout on the

straight roll. In this manner, there is a great deal less scrap because of the predictability of the operation and because the straightening itself is done so that the mandrel will be easily withdrawn from the tube. Therefore, this is an indirect scrap reduction; however, it has been proven that it is much more gentle on the tube wall than the so-called cross-rolled derodder, where the straight roll is rammed into the center of the concave roll, and plain, raw pressure ovals the tube and pressure-irons it out with stresses against the hardened mandrel. This savings results later on when the material is straightened by other means, generally, six-roll machines if it is not to go into screw machines or other applications.

The reduction of scrap in the straightening process of tubing depends on the method of manufacture of the tubing. The simple straightening of large-diameter tubes (approximately 127 mm, or 5 in., with a heavy wall of approximately 16 mm, or  $\frac{5}{8}$  in.) that are used in trailer axles, for example, was done in a multiroll or on a gag press. Experiments indicate that the rotary straightening of these in a two-roll machine will increase their fatigue life more than five times. Thus, scrap reduction by straightening is enhanced by the selection of the proper straightening method.

# Forming of Wire

Revised by David Berardis, Fenn Technologies

WIRE FORMS are used to give a high strength-to-weight ratio, an open construction (as in fan guards or baskets), resilience to absorb shock, and the economy of automated production of formed parts. When production quantities are small or the size of the finished article is large, the wire may be straightened and cut to length as a preliminary operation before the individual pieces are fed into hand benders, kick presses, power presses equipped with appropriate dies, or coiling devices. For large quantities, the wire is straightened as it comes from the coil and is fed directly and continuously into power presses, automatic forming or spring-coiling machines, multiple-slide machines, or special machines actuated by cams, air, or hydraulic cylinders. Wire drawing is discussed in the article "Wire, Rod, and Tube Drawing" in Volume 14A of the *ASM Handbook*, 2005.

Operations other than bending that are performed on wire include:

- **Threading** with single-head or multiple-head chasers, or with flat-die or rotary-die roll threaders. Roll dies can also be used for knurling, pointing, and chamfering.
- **Heading** in open-die rod headers, to make a variety of heads such as flat, round, slotted, indented hexagon, tee, and ball
- **Swaging or extruding** of long points or reduced-diameter sections on rotary-die swagers, stationary-die swagers, or long-stroke headers. While rotary swagers are used for pointing and reducing the diameter, stationary-die swagers are used to produce flattened ends, such as for screwdrivers and chisels.
- **Welding** with resistance, arc, or gas

**Speed of Forming.** Increasing the speed of forming can result in out-of-tolerance parts, increased springback, and wear on the tools and machine caused by increased force and torque. With older machines in which some of the tools are air-actuated and some are not, enough time must be allowed for the air-actuated tools to cycle to prevent the machine from going out of phase. For example, a machine with a mechanical drive and air-actuated tools was constantly out of phase when the production rate was increased. By reducing the speed slightly, the air valves and cylinders had time to complete their

cycles and were in phase with the mechanical devices. Higher speeds can be achieved using servo motors and drives rather than the more antiquated pneumatics.

**Tools** used for forming wire should be made of tool steel hardened to 56 to 61 HRC. Water-hardening tool steels such as AISI W1 are usually adequate. For more severe forming and longer tool life, D2 tool steel is recommended. For forming wire at higher temperatures, that is, over 540 °C (1000 °F), H-13 tool steel is recommended. Surfaces contacting the wire should be polished to prevent marking. They can usually be hardened after tryout in the soft state. For operations that induce shock loading, such as repetitious swaging, an S-7 tool steel is recommended to prevent cracks from prematurely developing.

**Springback** is variable and difficult to control in the forming of wire, as it is in most press-working operations. Springback varies with the type and temper of wire and may be different for each lot of a specific type and temper. The most practical way to determine springback is to make trial bends either before the tools have been hardened or on temporary tools. The necessary final correction for springback is usually made at the final tool setup, after the tools have been hardened.

## Effect of Material Condition

Most wire forming is done at room temperature. Wire made of low-carbon steel is usually formed in the as-drawn condition. Medium-carbon steel wire (1035 to 1060) is usually annealed before severe forming and heat treated after forming.

**Surface Finish.** A rough surface on the wire may cause short tool life. Plated wire is as easily formed as is bare wire, except that if the plating loosens or peels, it may damage the tools. Platings of gold, tin, solder, or other soft metals may show marks readily; however, soft plating may act as a lubricant during the forming of wire. Whether the wire can be plated before forming may depend on the severity of forming and the subsequent fabricating operations. Welding, for instance, may require that plating be done after forming.

**Properties.** The strength of wire is important in forming, especially when making steel springs. The required tensile strength is developed in spring wire either by cold drawing through a series of dies with up to 85% reduction in cross section, or by heat treating steel containing 0.60 to 0.70% C, quenching in oil, and tempering the wire. The elastic limit in torsion of spring wire is more important to its use in a spring than is its tensile strength. Information on the mechanical properties of steel spring wire is available in the article "Steel Springs" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of *ASM Handbook*, 1990.

## Rolling of Wire in a Turks Head Machine

A Turks Head machine (Fig. 1) generally has four rolls that will accommodate wire of one cross section (generally, round) and cold roll it to another shape. A Turks Head may be compared to an adjustable draw die but is actually infinitely adjustable within its limiting dimensions. The Turks Head operates on the rolling mill principle and imparts the same qualities to the metal as the rolling mill does, namely superior surface finish, accurate size and shape, and improved grain structure of the metal. Uses of the machine are:

- To make accurate square and rectangular wire directly from round wire
- To finish special shapes from round or preformed rough shapes
- To put edge contours on flat metal ribbon or rectangular wire

**Operation.** The machine has a cluster of four rolls with the four axes in the same plane and at right angles to each other, as shown in Fig. 1(a) and (b). In operation, a coil of wire is supported in a pay-off reel; the wire is pulled through the rolls by a capstan and then recoiled. A draw-bench can be used for pulling short lengths (up to 30 m, or 100 ft) through the rolls, while a capstan or drawing block is used to pull through continuous lengths of wire. Larger Turks Heads can be powered by driving the upper and lower roll assemblies. The power-driven Turks Heads eliminate the need for a pull-through device.

This is advantageous for forming irregular shapes that distort when coiled, for materials of low tensile strength, or precious metal wire where the leader cannot be wasted in threading.

Depending on the shape to be formed, the narrow rolls can be centered (opposed), as in Fig. 1(a), or they can be offset, as in Fig. 1(b). Although the rolls shown are plain cylinders, these can be replaced with rolls ground to any shape that will form the desired cross section. Some sections require several passes through the machine. It may take two passes to roll an accurate sharp-cornered square wire, and three or more passes may be needed to make a complex section fill properly.

Simple or complex shapes may be drawn through a standard Turks Head machine as fast as 180 m/min (600 ft/min), depending on the force and speed available in the capstan or drawbench and the amount of heating in the operation. A standard Turks Head contains needle bearings in its roll assemblies. High-speed Turks Heads use tapered roller bearings in the roll assemblies, which allows for higher speeds with the trade-off of lighter loading. Wire can be drawn through a high-speed Turks Head at speeds of up to 450 m/min (1500 ft/min), although these Turks Heads are limited to lighter reductions than standard Turks Heads. In general, the sections that can be formed depend on the ductility of the wire and are limited to shapes that can be ground into the rolls and shapes that are suited to the roll design, symmetrical, and no wider than twice the round wire thickness (unless preformed wire is used).

Some Turks Head machines have three rolls to make triangular shapes and other shapes suited to a three-roll design.

**Accuracy** of forming in a Turks Head machine depends on:

- Accuracy and uniformity of the initial round wire in size, shape, smoothness, hardness, and ductility
- Tensile strength of the incoming wire
- Dissipation of heat caused by cold working
- Smooth operation of drive in accelerating, running, and decelerating

- The amount of reduction in area or change in section in one pass
- Amount and type of lubrication used on the wire as it is formed

Any variation in size of the round wire pulled through the rolls may cause changes in size and shape of the product. If the round wire is oversize in a portion of its length, it may cause a sharper corner in the shape and thus a longer cross-corner dimension, or it may form a fin. If the round wire is undersize, the shape will not be well filled, and the cross-corner dimension will be decreased. Similarly, too heavy of a reduction will cause a fin in the corners, while too light of a reduction will lead to corners that are not well filled.

Variations in the hardness and ductility of round wire can also cause variations in the cross-corner dimension of a shape. Hard spots increase the cross-corner dimension; soft spots decrease it. A rough or unlubricated surface increases cross-corner size; a smooth, oiled surface makes it smaller. Heating of the rolls caused by cold working may enlarge the rolls, making the product smaller. A coolant is frequently used to remove heat from the rolls. Mineral oil is typically used in this application, because it is superior to water-soluble oil for lubrication.

Nonuniform acceleration, running and deceleration of the capstan, and changes in tension on the wire may also cause variations in the formed shape. The greater the reduction in section size of the wire as it is drawn through the rolls, the greater the chances of variations in the formed shape.

Tolerances in wire formed in a Turks Head machine in ordinary production are  $\pm 0.05$  mm ( $\pm 0.002$  in.), but  $\pm 0.013$  mm ( $\pm 0.0005$  in.) is a reasonable tolerance if all important factors are controlled.

## Spring Coiling

Production coiling is done in automatic spring coilers. In a standard spring-coiling machine, a pair of feed rolls pushes a calculated length of straightened wire through restricting guides

against a coiling point and around a fixed arbor into a coil. At the end of the coiling cycle, the feed rolls stop, and a cutoff mechanism actuates a knife, which severs the completed spring against the arbor. A flying knife separates the completed spring from the wire strand.

Modern spring coilers are computer numerical controlled (CNC) and use high-speed servo motors, servo drives, and computers to facilitate easy programming and easy operation. While traditional gear and cam mechanical spring coilers are limited in the types and sizes of springs they can produce, an automated CNC spring coiler can produce almost any kind of spring as well as extremely complex wire forms. A modern computer-controlled Torin spring coiler is shown in Fig. 2.

Standard spring-coiling machines range in size from those that can coil only fine wire to those that can form 19 mm ( $3/4$  in.) diameter cold-drawn or 16 mm ( $5/8$  in.) diameter pretempered wire. Each coiler can process a range of wire diameters, depending on the number and size of half-round grooves in the feed rolls. A set of feed rolls usually has grooves of three or four different sizes. For example, a machine may coil wire 2.3 to 5.36 mm (0.09 to 0.21 in.) in diameter and make a spring with an index (ratio of mean spring diameter to wire diameter) ranging from 3 to 18. The length of wire fed is controlled by the feed rolls.

A coiler equipped with a variety of attachments and cams or servo motors can produce almost any type of spring, including tight-wound extension springs, common compression springs with either open ends or ends closed for grinding, barrel-type springs of various contours, tapered springs, single-coil springs, variable-pitch compression springs, and torsion springs. A modern computer-controlled spring coiler can also produce an infinitely wide variety of bent wire forms.

**Setup time** is significantly reduced with modern CNC camless spring coilers, because these machines are very easy to set up. What used to take hours to set up with mechanical machines with cams and levers is now reduced to minutes on new CNC spring coilers. Now, small production runs can be profitable, because a

**Fig. 1** Turks Head rolls. (a) Positioned in line to form a rectangular cross section. (b) Offset to form a square section. (c) Machine section of a Turks Head roll

recalled spring can be quickly and accurately produced. Preset production count automatically stops the machine when the desired production run is reached.

New five-axis CNC springmakers are designed for a full range of traditional wire sizes but differ from the mechanical counterparts by being fully servo controlled. The feed, diameter, pitch, torsion, and coiling-point axes (Fig. 3) are directly driven with externally commutated alternating current brushless servo motors. There are no cams or associated levers and linkages used, and there are no motor brushes to wear out. Torque transmission on the diameter, pitch, torsion, and coiling point is done through preloaded ball screws, thus eliminating backlash effects. The servo motors

have a very high torque-to-inertia ratio to maximize responsiveness.

A tight-wound extension spring is wound in a standard coiler, but the end loops are formed in one of three ways:

- One or more of the end loops are opened up or pulled out in a secondary operation to form the required end hooks.
- End loops are automatically formed by deflecting the wire into shape as a part of the coiling operation.
- Automatic handling equipment and attachments are incorporated as additions to a regular coiler to make the loops.

The second method is less complicated to set up and operate, but both it and the third

method are limited to wire less than 1.25 mm (0.050 in.) in diameter and, because of setup time, to production runs of not less than 10,000 pieces.

A machine equipped with a torsion-spring attachment forms straight extended arms; these arms can be formed and looped as desired in a second operation.

Compression springs are wound in standard coilers equipped with a pitch tool located under the first formed coil. This tool, controlled by cams, regulates the spacing between the coils, which may be either uniform or variable. The ends of compression springs may be plain, plain and ground, square, or square and ground.

The use of round wire predominates in making compression springs, although square, rectangular, or special-section wire is necessary in some applications. For example, die springs are formed with rectangular wire. Square or rectangular wire is used to obtain the maximum load capacity for a given space. Wire with square corners before coiling will upset at the inside of the coil and become trapezoidal in section after coiling. This limits the deflection per coil, especially with small ratios of mean diameter to wire thickness.

**Accuracy.** With older mechanical spring coilers, the cams, gears, and other parts of a coiling machine become worn as the machine is used, resulting in a less accurate product. Some product inaccuracies can be reduced by control of the speed of the machine. With newer CNC spring coilers with servo drives, there are no mechanical parts such as cams to wear out, so more accurate parts are produced in the long run. Additionally, servo motors and precision, hardened, preloaded ball screws on diameter, pitch, and torsion provide a zero backlash operation. Accuracy such as 0.013 mm (0.0005 in.) on feed and 0.0013 mm (0.00005 in.) on pitch, diameter, and torsion can be achieved.

Dimensional variations for different materials are caused by variations in springback and by distortion during heat treatment. Variations in pitch and diameter depend on the speed of coiling. Dimensional variation depends also on the ratio of wire size to diameter and the ratio of pitch to spring diameter. By increasing the limits slightly, coiling speed and production rate may be increased.

Many springs are acceptable with inaccuracies or with a wide tolerance in dimensions and performance, but some springs (valve springs, for instance) must be more accurate. Variations in mechanical properties of wire will result in nonuniform springs. Standard spring wire has a permissible tensile-strength variation of 170 to 240 MPa (25 to 35 ksi); wire for valve springs has a limit of variation of 140 MPa (20 ksi). The range for any one coil seldom exceeds 35 MPa (5 ksi).

Coiling must be fast enough to produce an even flow of wire from the pay-off reel. If the wire flow is jerky or nonuniform, the dimensions of the spring may vary excessively.

Manual and Power Bending

Manual and power bending are done in rotary benders, pneumatic or hydraulic formers, and special fixtures to locate the bend and hold the part. The blanks are straightened and cut to length before forming.

A rotary bender can be either manual or power operated. The precut blank is placed between a center pin or form block and a stop pin. The arm supporting the wiper block is rotated clockwise, thus forming the wire around the center pin. An adjustable stop controls rotation of the arm so that uniformity is maintained from piece to piece. The eyebolt shown in Fig. 4 was formed in a rotary bender from 13 mm (1/2 in.) diameter cold-drawn stock at a production rate of 300 pieces/h.

The center pin can be changed to suit the bend radius. Form blocks can be used for larger radii. The stop pin is movable to accommodate different bend radii and stock thicknesses. Round, square, or rectangular wire can be bent in this equipment.

A more complex wire form, such as the scroll shown in Fig. 5, can be formed around blocks mounted in a rotary bender. The compact shape at each end could be formed by holding the wire taut while it is wrapped around a rotating form block, or in a machine with a spring-loaded or air-loaded wiper block. Another form block could be used for the long curves. The form blocks in these two operations must be designed to compensate for springback. The sharp bends at the outer ends can be made in a rotary bender around a center pin. Many types of complex wire forms can also easily be formed by a modern computer-controlled spring coiler.

The CNC servo hydraulic three-axis wire bending machines can automatically take wire directly from the coil, straighten it, make any number of bends through any angle and curvature and in any plane, and cut the finished product. The three-axis CNC wire bender can handle mild steel, spring steel, or aluminum wire from 2 to 7 mm (0.08 to 0.27 in.) in diameter. Bending is by a single head that rotates to give the third dimension. When the wire diameter is unaltered, changeover from one bend to another can take as little as 5 s, because bending programs are stored in a built-in memory. When the wire diameter varies, changeovers can be accomplished in approximately 15 min.

Forming in Multiple-Slide Machines

Multiple-slide machines are automatic mass-production machines that make completed wire (or sheet metal) products from coiled stock. They can straighten, feed, cut, stamp, and form the wire, all in one continuous operation. Attachments are used for additional operations on wire up to 13 mm (1/2 in.) in diameter. Feed lengths of wire used to make one part may be as much as 1 m (3 ft).

Most multiple-slide machines are horizontal, but some are vertical and some are inclinable. Production lots of 10,000 pieces usually justify the use of a multiple-slide machine, but smaller lot sizes may also be economical.

A multiple-slide machine usually includes a wire straightener, feed mechanism, and stock clamp and has a bed with four or more forming slides, a center post, and a stripper. Traditional machines known as four-slide machines in fact have four separate forming slides. New modern multislide machines may have as many as eleven independent forming slides. Some of these slides may be replaced with welding heads, stamping heads, drilling and tapping heads, or others as needed, depending on the part to be made. More information on forming in multiple-slide machines is available in the article "Forming of Steel Strip in Multiple-Slide Machines" in this Volume.

Production Problems and Solutions

Examples of several wire-forming production problems and solutions are given in Table 1.

Fig. 4 Eyebolt formed in a rotary bender. Dimensions given in inches

Lubricants

Requirements of lubricants for wire-forming operations are more severe than for most other metalworking operations. The exceptionally high working pressures that may be reached require special lubricants to prevent galling, seizure, or fracture of the wire, as well as excessive tool wear. Improper lubricating oils or compounds interfere with close-tolerance work and cause variations in the finished parts. The lubricant varies with the type of wire. Aluminum, copper alloys, basic steel wire, and steel spring wire each require a different lubricant. Lubricants for wire forming can generally be classed in three groups: inorganic fillers, soluble oils, and boundary lubricants.

**Inorganic fillers** include solids such as white lead, talc, graphite, and molybdenum disulfide in a vehicle such as a neutral oil or paraffin oil.

**Soluble oils** include mineral oils to which agents such as sodium sulfonates have been added to make the oil emulsifiable in water. Soluble oils are good for cooling and corrosion prevention.

Fig. 5 Complex wire scroll formed in a rotary bender. Dimensions given in inches

Table 1 Wire-forming production problems and solutions

Problem	Solution
A small garment eye was produced at the rate of 300 parts/min, but desired flatness was not obtained. The eye was to be formed in one plane.	The tooling was changed to form the eye on a plate, confining the wire. Forming sections were supported in the plate and were retracted below the surface of the plate before ejection.
Broaching of a flat on a small formed part for a business machine caused fine chips to collect in the forming tools, interfering with the work.	Forming was done on the upper level, and broaching was accomplished on the lower level of the machine. A small jet of air blew the chips down and away from the forming tools.
A small electronics part was formed around a fragile center post that broke after a few thousand pieces were formed.	The tooling was changed so that the part was made in two stages. A heavy center post was used for the first form, where the greatest pressure was exerted. A center post having the shape of the smaller section controlled final closing of the part.
Ordinary forming tools could not form brass wire of 1.0 mm (0.040 in.) diameter into a 9.5 mm (0.375 in.) outside diameter ring.	The formed ring was sized by being pushed through a die below the forming level, by means of a ring-setting attachment.
Steel wire 5.7 mm (0.225 in.) in diameter was formed into seat wire in a large multiple-slide machine, using an 860 mm (34 in.) feed length. The front tool was 510 mm (20 in.) wide. The bearings of the front shaft became hot, and the cam roller of the front forming slide had to be replaced often.	The addition of auxiliary front slides at each side of the standard front slide provided more direct application of the forming pressure, with three motions from the front position, reducing the load on each tool. Forming loads were exerted at different points in the machine cycle, reducing bearing pressure and allowing faster machine speed.
A specially arranged multiple-slide machine for forming and welding handles from low-carbon steel wire 2.4 mm (3/32 in.) in diameter made imperfect welds. There were also variations in forming. The wire varied in diameter and tensile strength, which affected the feed length and forming. Operators had not been trained to adjust and maintain the machine.	The wire was specified to closer tolerances and inspected before use. Operators were trained, and a program of preventive maintenance was initiated. Production efficiency increased to 75% from as low as 25%.

**Boundary lubricants** are thin, absorbed films and are usually subjected to high unit pressures. Thin-film lubricants are of two basic types:

- *Polar lubricants:* lubricants, or constituents of lubricants, capable of either physical or chemical adsorption on a solid surface to form a thin film that resists mechanical removal and provides lubrication under high unit pressures
- *Extreme-pressure lubricants:* lubricants capable of reacting chemically with solid surfaces under rubbing conditions, to prevent welding and provide lubricant reaction products on the surface. Extreme-pressure lubricants permit high unit loading with a minimum of surface wear and damage.

Chemically active constituents of typical boundary lubricants are sulfur, chlorine, and phosphorus compounds.

**Applications.** Certain types of oil, wax, and tallow are used to lubricate aluminum and scaly steel wire. Mixtures of lard oil or of paraffin oil in kerosene, or of oil and a soap solution, have been used as lubricants for wire forming.

Often, the lubricant used in drawing wire is expected to stay on the drawn wire in a

quantity that is adequate for subsequent forming operations. Many severe operations, such as upsetting and spring coiling, may be done without additional lubrication, but additional lubricant may be used in some press and rolling operations.

The lubricant remaining after wiredrawing should be enough to lubricate a wire formed over a form tool or a mandrel. The lubricant should be a hard, dry coating, such as a mixture of lime and metal soaps. This will protect the wire from damage in forming and will extend the life of the tools without sticking to them.

Zinc phosphate is often used to coat wire before it is redrawn into smaller sizes. It is also used in coiling thick, high-tensile spring wire into a closed helix. In other difficult forming, such as a large upset, a zinc phosphate coating is a good lubricant for all tools.

Wire for forming into products to be electroplated is usually drawn with a lubricant that can be easily removed and that does not contain small particles that could become embedded in the surface of the wire. After drawing, the wire may be sprayed or dipped in thin oil. The oil protects the wire from corrosion and serves as a lubricant in the forming operations.

Steel wire with a metal coating, such as zinc, tin, copper, brass, or lead, is often used in forming. In some operations, the metal coating provides all the lubrication necessary.

When lubricant must be added to the wire, it can be applied at the uncoiler or at the tools. Soluble oil or wax in water is most practical and is easy to remove in cleaning. Some formed wire must be completely clean.

Spring wire is supplied with a coating that acts as a lubricant. The coating may be a mixture of soap and lime or of borax or phosphate, or it may be a plating (or displacement coating) of cadmium, zinc, tin, or copper. When the coil is to be electrically normalized, a borax coating is specified; other coatings insulate the wire from good electrical contact.

The most unusual lubricant may be the one that comes on the oil-tempered grade of valve spring wire. During heat treatment, oxidation of the surface is permitted under carefully controlled conditions. The scale thus formed acts as a lubricant during coiling. Its characteristics must be carefully controlled with respect to thickness, adherence, and flakiness, because not only must it supply the required lubrication during coiling, but it should detach from the surface at the same time.

# Forming of Carbon Steels

Revised by Mahmoud Y. Demeri, FormSys Inc., and Steve Lampman, ASM International

---

FABRICATION of sheet products includes various forming operations such as press forming, press bending, press-brake forming, stretch forming, and deep drawing. Fabrication of sheet products may also include cutting operations, such as blanking, trimming, and piercing (for example, see the articles “Blanking of Low-Carbon Steel” and “Piercing of Low-Carbon Steel” in this Volume).

The choice of forming method depends on the desired size, configuration, and production quantities of a part. For example, press forming (where a punch presses the workpiece into a die) is widely used and is often the most effective method when production quantities are large and workpieces are relatively small. In some applications, however, other forming methods may be desirable or needed. For example, the production of hollow shells from flat blanks requires deep drawing, where sheet is pressed into a die opening to draw the metal into the desired shape without folding of the corners (see the article “Deep Drawing” in this Volume).

Another example is press-brake forming, which sometimes is the only practical method of producing a given shape. Compared to press forming, press-brake forming is more effective when only a few pieces are needed or when the workpiece is large. Tooling for a press brake (see the article “Press Brakes” in this Volume) is usually simpler and less costly than counterpart tooling for a punch press, and so it can be effective for small production quantities. Press brakes are also more effective as the size of the workpiece increases. Presses are usually used for workpieces less than 610 mm (2 ft) long, while press brakes are used for pieces longer than 610 mm (2 ft)—except perhaps in the automotive industry, where very large sheet metal parts are mass produced on large presses.

In general, press forming is often more economical than the press-brake forming method, because of high production rates and the efficient use of metal. When a given workpiece can be made to an equal degree of acceptability in either a press brake or a punch press, the punch press is usually more economical. The punch press is more efficient than the press brake in terms of power requirements for a given force on the ram and number of strokes per unit of time. Air ejection (of either the workpiece or scrap) also is

more readily adapted to a punch press than to a press brake. In addition, punch presses can be applied to produce various surface profiles, with forming conditions ranging from pure bending (press bending) to more complex forming conditions involving stretching, bending, and drawing.

This article reviews the selection and formability characteristics of steels, with emphasis on low-carbon steels and some coverage on the forming of high-carbon steels (which, despite the higher strength and lower ductility compared to other carbon steels, are formed into products requiring high strength, stiffness, and hardness). Low-carbon steels are the most commonly used sheet metal because of their low cost and good formability. However, ordinary low-strength, low-carbon sheet steel has been replaced by a number of higher-strength sheet steels requiring new process technology. These new steels include the high-strength, precipitation-strengthened steels, the dual-phase and tri-phase steels, and the bake-hardenable steels. Also, new coating techniques have been developed to protect these new steels from corrosion. These topics are discussed in more detail in the articles “Forming of Advanced High-Strength Steels” and “Press Forming of Coated Steel” in this Volume.

## Presses and Dies

The characteristics of the various types of presses used in forming sheet metal parts are discussed in the article “Presses and Auxiliary Equipment for Forming of Sheet Metal” in this Volume. Single- and double-action presses are available in approximately the same ranges of bed size and force capacity. Restriking, coining, and embossing are usually done in presses with more available force capacity than that needed for the simple forming of similarly sized areas, because in these operations the metal is confined while being forced into plastic flow. Progressive dies are used in presses with enough force capacity to meet the total demands of the various stations and with enough dimensional capacity for the long multiple-station dies. Although some progressive dies are hand fed, most have auxiliary equipment, such as stock feeders, scrap

choppers, coil reels, and chutes, to carry the finished parts to containers. The use of blank feeders and piece ejectors or extractors depends on the production rate and safety requirements. Springs, cams, fluid pressure, or press knockouts are used for piece ejection.

Shallow forming can be done in single-action presses using die cushions or springs to provide the blankholder pressure. Deeper forming and the forming of large, irregular shapes generally must be done in double-action presses with die cushions. The trend in stamping technology is to use single-action and transfer presses with hydraulic multipoint cushion systems in the press table (Ref 1). Multipoint cushion systems (Fig. 1) make it possible to control material flow between the binders of draw dies, due to closed-loop controls that automatically adjust blankholder forces according to changes in parameters affecting friction (e.g., lubrication, blank surface, die roughness, etc.).

The hydraulic four-point cushion (Fig. 1b) system is mainly a passive system, in that the pressure in the four cylinders increases by compression when the lower binder is forced downward. It is also possible to separately control pressure for each cylinder. It has also been shown that single-action presses with hydraulic four-point cushions give better and more reproducible draw results than mechanical double-action presses (Ref 1). Whether or not a press has a die cushion has some effect on die design and construction costs. Special die designs are needed to take advantage of hydraulic cushion technology.

**Speed of forming** has little effect on the formability of steels used for simple bending or flanging or for moderate stretching. The maximum velocity of the punch when it contacts the blank in such conventional press forming is usually not greater than approximately 1 m/s (200 ft/min). However, the steels used for most parts that involve local stretching of more than 20% in forming move considerably over the face of the punch or flow appreciably over the blankholder. The flow of the metal in such operations is controlled by frictional forces, and so, stretching failures can be sensitive to speed. The critical value differs for each steel and die combination, but a maximum punch velocity of 0.2 m/s (40 ft/min) is

recommended; high punch speeds also shorten tool life.

## Dies

Low-carbon steel can be formed by any of several types of dies. Bending dies include V-dies, wiping dies, U-bending dies, rotary bending dies, cam-actuated flanging dies, wing dies, and compound flanging dies (see the section "Bending Dies" in this article). Dies may also be designed for single-operation function, or multiple forming functions can be implemented more efficiently with the design of compound dies, progressive dies, and transfer dies (see the subsequent information). Dies for press brakes are discussed in more detail in the article "Press-Brake Forming" in this Volume.

Workpiece size and shape, production volume, tolerances, and available presses are the major factors that determine the most suitable type of die for a specific application. Dies for the press forming of low-carbon steel are made from a wide range of materials, including plastics, cast irons, tool steels, and cemented carbides. Severity of forming, number of parts to be produced, workpiece shape, work metal hardness, specified surface condition, and tolerances affect selection of the die material (see the article "Selection of Materials for Press-Forming Dies" in this Volume).

Simple bending dies are ordinarily subjected to less shock than other press-working tools; therefore, they can often be made of low-carbon steel, heat treated low-alloy steel such as 4140, or cast iron for low production of low-carbon steel pieces. For moderately high production, they should be made of flame-hardening grades of carbon steel, such as 1045, or flame-hardening cast iron, such as class 40 gray iron. Cam-operated dies, wiping dies, and dies used to make curved flanges (shrink or stretch) must be made of a higher grade of material. Tool steels such as O1 or A2 are used for moderately long produc-

tion runs. For a total tool life of 1 million or more pieces, D2 tool steel is used.

Bending dies used in press brakes can generally be used in presses. However, because presses ordinarily are not long and narrow like press brakes, more consideration must be given to clearance for removing the finished workpiece when the press is open, as well as clearance for the legs of the bend when the piece is being formed. The bed dimensions of a press also limit the size of workpiece that can be bent.

Presses also cycle more rapidly than press brakes, and the shut height is not as easy to change; therefore, fewer pieces are bent in air. More frequently, pieces are formed by bottoming the dies. This has the advantage of decreasing springback. One disadvantage of punch presses is that they are more sensitive to thickness variations of the work metal, because they operate at a faster rate than press brakes.

**Die Development and Press Setting.** To help identify problems during computer modeling and tool development and die tryouts, it is helpful to use steel near maximum in hardness and near minimum in formability. Tools developed with tryouts of below-average-quality steels are less troublesome for production runs and are less sensitive to pressure adjustments, variations in sheet thickness, or normal variations in steel properties.

After the dies have been manufactured, finished to a high polish, and mounted in the press, the first job is to "bed-in" the blankholder with the die plate. It is most important that neither the blankholder nor die plate have any high spots that may locally restrain the blank and prevent even flow of material during the draw.

Secondly, all the radii should be checked to ensure they blend in smoothly, then a blank, cut to the shape as predicted by the rules for blank size and shape, should be tried in the press. A lubricant should be selected to suit the operation. For deep drawing a good-quality drawing compound or for tapered shells where restraint by the blankholder is needed, a lubricant that prevents

galling of the sheet steel to the press tools but that has a relatively high coefficient of friction will be more suitable. After a few blanks have been drawn and the trouble spots identified, a series of blanks may be marked with circles for grid analysis of formability.

**Single-operation dies** perform one operation at a time and are individually loaded and unloaded. Single-operation dies are used for low production or on pieces that are so difficult to bend that only one operation at a time is feasible. Some single-operation dies are general-purpose dies that can make bends in simple workpieces of many different designs. Others are single-purpose dies for a particular piece.

Single-operation dies are usually set up in a press, and the operation is performed on a specific lot size. The die is then removed from the press, and the next die in the sequence is set up. For continuous production, a line of presses, each operating a single die, can produce finished pieces from raw stock without interruption for change in setup. Occasionally, more than one die is set up in a press at a time, and the parts are moved manually from one die to the next. With this type of tooling, more than one operation is done in each stroke of the press.

Single-operation press forming dies are used when:

- The operations are so interrelated that they cannot be done in a compound die.
- The amount of work done on a part is approaching press capacity, and more work would overload the press.
- Production quantity is low, and two or more single-operation dies would be less costly than a die combining operations.

Forming presses with single-operation dies do not necessarily have a low production rate. They often can be run at high speed with automated materials handling (e.g., coil stock fed automatically into blanking dies) or inclined beds (that permit high-speed loading and unloading). When a higher rate of production is needed, it is sometimes more practical to increase the speed of the press than to use an additional die, provided the flywheel, bearings, gibs, and gears can withstand the additional speed.

**Compound dies** are one-station dies in which more than one operation is done without relocating the workpiece in the die. One or more of the operations done in the die can be bending. The operations must be such that their inclusion does not weaken the die elements or restrict other operations.

Although the operations are generally done in succession in the course of the press stroke (rather than simultaneously), the operations may sometimes be done in one press stroke, so that a finished piece is produced with each stroke of the press. The press speed (strokes per minute) for compound dies is generally only slightly lower than for single-operation dies; therefore, production time and labor cost per piece are decreased almost in proportion to the number of operations done in the compound die.

**Fig. 1** Single-action press with draw cushions in the press table. (a) Pneumatic draw cushion. (b) Hydraulic draw cushion. Source: Ref 1

Typical combinations of operations include:

- Cutting a blank from a strip and then forming
- Lancing and forming a tab or louver
- Forming a flange and embossing a stiffening bead

When a die is used for blanking and forming a part, holes can often be pierced in the bottom with the same die. When pierced holes are required in a flange, piercing should be done after the flange has been formed; otherwise, the hole (and perhaps the edge of the flange) can be distorted. The combination of lancing and forming is common. Continued travel of the lancing punch does the forming. Flanging can be combined with forming or embossing if no metal flow is necessary after the flange has been formed.

A compound die may or may not cost more than a set of single-operation dies. Loading and unloading can be automated or manual. Compound dies are generally operated at slower speed than single-operation dies. In the automotive industry, single-operation and compound dies are both set up in a press line. Coil stock or blanks are automatically fed into the first press, and the workpiece is automatically removed and transferred to the next press, where the cycle is repeated until the workpiece is completed. Typical parts are front grills, hoods, roof panels, and deck lids.

Several operations can be performed successively on a workpiece in a press, using two or more compound or single-operation dies. The parts can be manually transferred from die to die, eliminating storage and transfer between presses. The capacity of a large-bed press may be more fully used by performing several operations during each press stroke.

In most applications, the cost of a compound die does not differ greatly from the combined cost for equivalent separate dies, and is sometimes less. Operations must be judiciously combined in making a compound die in order not to have die sections that are too thin to be heat treated without distortion, or that will break down under the cyclic loading of ordinary die operation. If these precautions are observed, die life and die maintenance costs should be nearly the same as the costs for equivalent simple dies. Compound dies can be fed individual blanks, or they can be fed strip stock.

**Progressive dies** are similar in function to compound dies in that they combine in one die set several operations that are performed with one stroke of the press. In a progressive die, however, the operations are separated and dis-

tributed among a number of stations. The stock progresses through these stations in the strip form until the finished workpiece is cut from the strip at the last station. Consequently, at the start of a strip, there are several press strokes before a piece is produced. Thereafter, a finished workpiece is produced with each stroke of the press, up to the end of the strip (Fig. 2). Tandem part production is shown in Fig. 3.

Although a progressive die runs more slowly than a single-operation or a compound die for similar work, overall production is usually higher because the die is operated more continuously. The initial cost of a progressive die is generally greater than that of a series of individual dies for the same workpiece. However, unless the production quantity is low, the lower setup, maintenance, and direct-labor costs for the progressive die will often outweigh its higher initial cost.

The choice between a progressive die and two or more separate dies (single-operation or compound) is not always clear-cut. Various considerations can influence the decision; perhaps the most important is the size of the production order. Other considerations are the rate of obsolescence of the product and the rate at which tool cost must be amortized. Example 2 (which follows) shows how these considerations can affect choice of type of die. In this example, increased annual production requirements justified the use of a progressive die.

A set of individual dies is sometimes used for making a complex part prior to the designing and building of a progressive die. This is done for two reasons. First, a set of individual dies can usually be made in less time than a progressive die, thus permitting earlier production startup, and second, the experience gained in producing the parts in individual dies can be used in designing the progressive die. From this experience, it can be determined:

- How the metal flows and reacts in the die
- How much work can be done in each operation
- What is the best sequence of operations
- What the size and shape of the developed blank should be

Progressive dies are used to perform an almost endless variety of operations on one piece. Operations that can be combined in a progressive die include notching, piercing, coining, embossing, lancing, forming, cupping, drawing, and trimming. As the outline of the workpiece is developed in the trimming or forming stations, connecting tabs link the workpiece to the strip

until the workpiece reaches the last station, where it is cut off and ejected from the die. Pilot holes that are engaged by pilot pins in the die keep the workpieces aligned and properly spaced as they progress through the die.

If the strips are short, sheared from sheets, they can be fed into the die so that each strip is butted against the end of the preceding strip for continuous production. Otherwise, starting stops are used for each new strip. Coil stock is fed into the die at one end. A hole or notch is usually made in the strip at the first station, and subsequent stations use this as a pilot to keep the strip properly aligned and positioned while the operations are performed. When the workpiece is complete, it is cut from the strip, which has acted as a holder to carry the piece from station to station. Intricate pieces, often needing no further work, can be made in one press.

In planning the strip layout for progressive-die operations, consideration must be given to development of the part outline, to provision for piloting, to distribution of press load and strength of die elements, and to ensuring minimum metal waste. Some compromise among these factors is usually necessary in developing a sequence of operations and designing a progressive die to accomplish these operations. The strip layout in the following example (example 1) used the metal efficiently by having the developed flanges surround the body of the preceding part.

**Example 1: Nesting of Workpieces to Minimize Stock Waste.** The bracket shown in the lower part of Fig. 4 was formed from hot-rolled 1010 steel strip in a progressive die with three working and two idle stations. As shown in the upper part of Fig. 4, pieces were nested on the strip to minimize scrap. The operations in the three working stations were as follows: pierce one pilot hole and two flange holes and notch the contour, bend two tabs upward, and flange and cut off from the center connecting tab.

The die was used in a 1330 kN (150 tonf) mechanical press that could make 50 strokes per minute. Allowing for setup and downtime, production was 2800 pieces per hour. A light mineral oil was the lubricant.

where it is first severed by a cutoff mechanism to predetermined lengths. The piece is usually formed around a center post by four sets of tools mounted 90° apart around the forming post.

Fig. 7 Classic gripper system in a transfer press

Finally, the part is stripped off the center post and dropped through a hole in the bed.

Small parts that are used in large quantities and require considerable forming are often

produced on multiple-slide machines. In general, more severe forming can be done in the forming station of a multiple-slide machine than in a progressive die. The following example illustrates high-carbon steel parts produced in a multiple-slide forming machine. Additional information on multiple-slide forming is available in the article "Forming of Steel Strip in Multiple-Slide Machines" in this Volume.

**Example 4: Blanking and Bending a Bracket in a Multiple-Slide Machine.** The mounting bracket shown in Fig. 11 was embossed, pierced, and notched in a progressive die in the press station of a multiple-slide machine. It was then cut off and bent. Production was at the rate of 100 pieces per minute. The work metal was coiled cold-rolled 1050 steel strip, 0.91 mm (0.036 in.) thick by 32 mm (1¼ in.) wide.

In the press station, two holes were pierced, two weld projections were embossed, one hole was flanged, the outline was notched, and the top surface was flanged to improve stiffness. The strip then moved to the forming station, where the part was cut off and bent to the final form shown in Fig. 11. All slides in this station moved in a horizontal plane. A front slide tool held the part against the center post and preformed the flanges. A cam action on the right and left slides formed the flanges against the post and the rear slide tool.

## Lubrication

**Lubrication in Bending.** Lubrication is less important for most bending operations than for other types of forming. In many bending operations, no lubricant is used; in others, the mill oil remaining on the stock or a light mineral oil applied before forming is sufficient to prevent galling. Exceptions to this practice are hole flanging, compression and stretch flanging, and severe bending in which wiping, ironing, or drawing of the work metal may call for more effective lubrication. An application in which lubricants were used because of the nature of the bending operations is in example 5, in which accuracy was important and sharp-radius bends were made parallel with the direction of rolling; the workpiece was lubricated with mineral oil before bending. Another example may be lubricant applied to a workpiece before hemming or flattening a bend to 180°.

Fig. 11 Mounting bracket that was blanked and bent in a multiple-slide machine. Dimensions given in inches

**Example 5: Bending Parallel with Rolling Direction.** Conflicting demands called for a choice in the orientation of the blank for the can-opener blade shown in Fig. 12. Because an orientation that would favor the bends would have meant a cross-grain surface on the cutting edge, with consequent poor wearing quality, the blank was oriented so that the grain favored the cutting edge, and the bends were made nearly parallel with the direction of the rolling.

To ensure that the stock would withstand the three sharp-radius 90° bends, the steel specification called for stock that would withstand a 180° bend both parallel with and across the direction of the rolling. Steel that could be oil hardened was specified in order to limit distortion during subsequent heat treatment. A modified 1023 steel (with 0.85 to 1.15% Mn) met all of the requirements. The stock was 50 mm (2 in.) wide cold-rolled strip 1.1 mm (0.045 in.) thick. A No. 2 finish was specified to minimize the amount of polishing or burnishing before plating.

The blade was made in a 12-station progressive die, run in a 670 kN (75 tonf) mechanical press. Operations performed in the die included:

- Pierce four holes (one in the scrap area served as a pilot hole)
- Notch outline of part
- Coin cutting edge
- Emboss center hole
- Form bends
- Cut off

The die was made of D2 tool steel, except for the bending and cutoff station, for which the die material was C-5 carbide at 71 HRC. The die life per grind was 300,000 pieces. Mineral oil was the lubricant.

The production rate was 4500 pieces per hour. Annual production was 8 million pieces, in 700,000-piece lots. After forming, the part was oil hardened, barrel finished in oil and sawdust, and bright nickel plated.

**Lubrication in Press Forming.** The type of lubricant used usually has little effect on the grade of steel selected to form a given part. The main purposes of a lubricant are to prevent die galling and die wear and to reduce the

friction over critical areas, thus allowing proper flow of metal and possibly a reduction in severity class. The selection of the optimal lubricant for a given part is a complex problem that depends on part geometry and the forming process used.

In progressive dies, a light oil sprayed on the strip as it enters the die is often enough to keep the stock lubricated through all stages. The oil is generally applied to the stock between the feeding device and the die. Applying oil to the stock ahead of the feeder may cause variation in the feed length, depending on the type of feeder.

For some applications, residual mill oil or the residue from emulsion cleaning provides enough lubrication for forming. When this is not adequate, a spray or mist lubricant can be applied to the work metal as it enters the die. More information on lubricants is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

## Sheet Steels

Steel sheet selection should be based on an understanding of available grades of sheet and forming requirements. Other factors that should be considered when selecting a material for forming into a particular part include:

- Purpose of the part and its service requirements
- Thickness of the sheet metal and allowable tolerances
- Size and shape of blanks for the forming operation
- Equipment available for forming
- Quantities required
- Available handling equipment for sheets or coils
- Local availability of sheet products
- Surface characteristics of the steel sheet
- Special finishes or coatings for appearance or for corrosion resistance
- Aging propensity and its relation to time before use
- Strength of the steel sheets as-delivered
- Strength requirements in the formed part

Because these factors may be interdependent, technical representatives of suppliers or the steel producer should be consulted, especially if steel selection is for either large quantities or special requirements. Some parts require specialized low-carbon steel that has been processed to enhance a given mechanical property and/or reduce production costs and forming problems.

Low-carbon steels, coated and uncoated, are generally supplied as commercial-quality, drawing-quality, and drawing-quality special-killed grades. Typical mechanical properties of low-carbon sheet steels are given in Table 1. Some steel mills also offer specialized grades, such as interstitial-free deep-drawing steels and enameling steels. Grade designations of common formable grades include:

- Commercial-quality (CQ) steel
- Drawing steel (DS)
- Extra-deep-drawing steel (EDDS)
- Extra-deep-drawing steel plus (EDDS+)
- Structural steel (SS)
- High-strength low-alloy (HSLA) steel
- Dent-resistant (DR) steel
- Bake-hardenable (BH) steel
- Inclusion-shape-controlled steel

General forming characteristics of the more commonly used formable grades are:

- *Commercial-quality (CQ) steel:* Available in hot-rolled, cold-rolled, and coated grades. The least expensive grade of sheet steel. Subject to aging (mechanical properties may deteriorate with time). Not intended for difficult-to-form shapes
- *Drawing steel (DS):* Available in hot-rolled, cold-rolled, and coated grades. Exhibits better ductility than CQ-grade steels, but has low plastic-strain ratio ( $r$ ) values. Subject to aging (mechanical properties may deteriorate with time). Has excellent base metal surface quality
- *Drawing-quality special-killed (DQSK) steel:* Available in hot-rolled, cold-rolled, and coated grades, with good forming capabilities. Not subject to aging (mechanical properties do not change with time)

**Fig. 12** Can-opener blade that was bent parallel with the direction of rolling in order to promote long service life of the cutting edge. Dimensions given in inches

**Table 1** Typical mechanical properties of low-carbon sheet steels

Quality level	Tensile strength		Yield strength		Elongation in 50 mm (2 in.), %	Plastic-strain ratio, $r$	Strain-hardening exponent, $n$	Hardness, HRB
	MPa	ksi	MPa	ksi				
Hot rolled								
Commercial quality	358	52	234	34	35	1.0	0.18	58
Drawing quality	345	50	220	32	39	1.0	0.19	52
Drawing quality, aluminum killed	358	52	234	34	38	1.0	0.19	54
Cold rolled, box annealed								
Commercial quality	331	48	234	34	36	1.2	0.20	50
Drawing quality	317	46	207	30	40	1.2	0.21	42
Drawing quality, aluminum killed	303	44	193	28	42	1.5	0.22	42
Interstitial-free	310	45	179	26	45	2.0	0.23	44

- **Interstitial-free steels:** Available in cold-rolled and coated grades, with excellent forming capabilities for deep drawing (as EDDS or EDDS+ grades)
- **Enameling steels:** Available in cold-rolled grades. Various types of processing are used to make a product that is satisfactory for porcelain enameling. All grades have good forming capabilities.
- **Structural steels:** When higher strength is required, structural-quality sheet, also called physical-quality sheet, can be specified, although at some sacrifice in ductility.
- **Higher-strength steel sheets:** Available in hot-rolled, cold-rolled, and coated grades. Various types of processing are used to obtain the desired strength levels. In general, the formability of these grades decreases as yield strength increases. Springback may be a problem at lower sheet thicknesses.
- **Inclusion-shape-controlled steels:** Cold formability has been substantially improved by inclusion-shape-controlled steels, which enables steel to be formed to nearly the same extent in both the longitudinal and transverse directions. Any grade produced with inclusion shape control can be more severely formed than a grade of the same strength level produced without inclusion shape control. Inclusion-shape-controlled steels are responsible for the moderately good formability of the higher-strength HSLA steels, such as the grades having 550 MPa (80 ksi) yield strengths.

**Low-carbon steel** sheet and strip are used for low-cost production of various products having good dimensional tolerance and appearance. The steels used for these products are supplied over a wide range of chemical compositions; however, the vast majority are unalloyed, low-carbon steels selected for stamping applications, such as automobile bodies and appliances. For these major applications, typical compositions are 0.03 to 0.10% C, 0.15 to 0.50% Mn, 0.035% P (max), and 0.04% S (max).

In the past, rimmed (or capped) ingot cast steel has been used because of its lower price. More recently, however, rimmed steels have been

largely replaced by killed steels produced by the continuous casting process. Continuous casting is inherently suited to the production of killed steels, but killed steels are also produced by ingot metallurgy. Regardless of the method of casting or manufacture, killed steels are preferred because they have better formability and are not subject to aging or strain aging (that is, mechanical properties do not change with time).

The width differentiation between sheet and strip made of plain carbon steel depends on the rolling process. It should be noted that both sheet and strip can be purchased as either cut lengths or coils. The standard dimensional tolerances for plain carbon steel strip are more restrictive than those for sheet. Standard size ranges of plain carbon steel sheet and strip are given in Table 2. Typical characteristics of the various qualities of these products are listed in Tables 3(a) and 3(b).

**Modified Low-Carbon Steel Sheet and Strip.** In addition to the low-carbon steel sheet and strip products, there are numerous additional products available that are designed to satisfy specific customer requirements. These products are often made with low-carbon steels having chemical compositions slightly modified from those discussed earlier. For example, in structural-quality (SQ) steels, alloying additions of manganese and phosphorus are used to increase strength by substitutional solid-solution strengthening: approximately 3 MPa (0.4 ksi) per 0.1% Mn, and 7 MPa (1 ksi) per 0.01% P. Hot-rolled SQ steels contain from 0.90 to 1.35% max Mn and 0.035% max P. Cold-rolled SQ steels contain 0.60 to 0.90% max Mn and 0.035 to 0.20% P. Carbon contents for SQ steels are generally 0.20 to 0.25%.

**Interstitial-Free Steels.** In interstitial-free (IF) steels, which are also referred to as extra-deep-drawing quality, the elimination of interstitials (carbon and nitrogen) is accomplished by adding sufficient amounts of carbide/nitride-forming elements (generally titanium and/or niobium) to tie up carbon and nitrogen completely, the levels of which can be reduced to less than 50 ppm by modern steelmaking/casting practices, including vacuum degassing.

Steels with very low interstitial content exhibit excellent formability with low yield strength (138 to 165 MPa, or 20 to 24 ksi), high elongation (41 to 45%), and good deep drawability. With the addition of carbonitride-forming elements, the deep drawability and the nonaging properties are further improved.

**Bake-hardening steels** are characterized by their ability to exhibit an increase in yield strength due to carbon strain aging during paint-baking operations at moderate temperature (125 to 180 °C, or 260 to 355 °F). Bake hardening has little effect on tensile strength. Bake-hardening steels are finding increased use in automotive outer-body applications (hoods, doors, fenders) to achieve an improvement in dent resistance and, in some cases, a sheet thickness reduction as well.

The bake-hardening behavior is dependent on steel chemistry and processing, in addition to the amount of forming strain and paint-baking conditions (temperature and time). Steels that exhibit bake-hardening behavior include plain low-carbon steels (continuously annealed or batch annealed), IF steels (continuously annealed), and dual-phase steels (continuously annealed).

Automotive specifications for BH steels can be categorized according to those that specify a minimum yield strength level or a minimum bake-hardening increment, in the formed (strained) plus baked condition. The conventional test for determining bake-hardening characteristics involves a 2% tensile prestrain, followed by baking at  $175 \pm 5$  °C ( $345 \pm 10$  °F). The resulting increase in yield strength measures the bake hardenability of the material.

While all the specifications call for a minimum yield strength level in the as-received (that is, prior to forming) condition, some also require a minimum yield strength after baking the as-received material in the absence of any tensile prestrain. The as-received yield strength is in the range of 210 to 310 MPa (30 to 45 ksi) (compared with approximately 175 MPa, or 25 ksi, for DQSK), while the final yield strength, that is, after 2% prestrain plus bake, ranges between 280 and 365 MPa (40 to 53 ksi)

Note: Incl, inclusive. (a) Cold-rolled sheet, coils, and cut lengths, slit from wider coils with cut edge (only) thickness 0.356–2.08 mm (0.014–0.082 in.) and 0.25% C (max) by cost analysis. (b) When no special edge or finish (other than matte, commercial bright, or luster) is required and/or single-strand rolling of widths under 610 mm (24 in.) is not required. (c) Width 51–305 mm (2–12 in.) with thickness of 0.356–2.08 mm (0.014–0.082 in.) are classified as sheet when slit from wider coils, have a cut edge only, and contain 0.25% C (max) by cost analysis.

(compared with approximately 225 MPa, or 33 ksi, for DQSK).

The HSLA steels are generally formed at room temperature using conventional equip-

ment. Cold forming should not be done at temperatures below 10 °C (50 °F). As a class, high-strength steels are inherently less formable than low-carbon steels because of their greater

strength and lower ductility. This reduces their ability to distribute strain. The greater strength makes it necessary to use greater forming pressure and to allow for more springback compared to low-carbon steels. However, high-strength steels have good formability, and straight bends can be made to relatively tight bend radii, especially with the grades having lower strengths and greater ductility. Further, high-strength steels can be stamped to relatively severe shapes, such as automotive bumper facings, wheel spiders, and engine-mounting brackets.

High-strength low-alloy steels can be hot formed. However, hot forming usually alters mechanical properties, and a particular problem that arises in many applications is that some of the more recent thermomechanical processing techniques (such as controlled rolling), used for plates in particular, are not suitable where hot forming is used during fabrication. This problem can be circumvented by the use of a rolling finishing temperature that coincides with the hot forming temperature (900 to 930 °C, or 1650 to 1700 °F). Subsequent hot forming therefore simply repeats this operation, and deterioration in properties is then small or even absent, provided that grain growth does not occur. Producers should be consulted for recommendations of specific hot forming temperatures and for comments on their effects on mechanical properties.

**High-Carbon Steels.** High-carbon steel strip (including spring steel and tool steel) is blanked, pierced, and formed to make a variety of parts. The practices, precautions, presses, and tools used in making high-carbon steel parts are comparable to those used for producing similar parts of low-carbon steel. The key differences in blanking, piercing, and forming of high-carbon steels compared to low-carbon steels include the following:

- Higher yield strength and lower ductility results in less bendability and, therefore, requires greater bend radii than plain carbon steels.
- Greater allowance is required for springback.
- More force is required for high-carbon steel because of its higher strength.
- Greater clearance between the punch and die is necessary in blanking and piercing.
- A more wear-resistant tool material may be required before acceptable tool life can be obtained.

In blanking and piercing of high-carbon steels, the most important difference with that of low-carbon steel is the need for greater clearance between punch and die (see the article “Blanking of Low-Carbon Steel” in this Volume). Mold forming of high-carbon steel in the quenched-and-tempered (pretempered) condition (usually 47 to 55 HRC) is common practice. The severity of forming that can be done without cracking of the work metal depends mainly on thickness. When metal thickness is no more than approximately 0.38 mm (0.015 in.),

Source: Ref 2

it is possible to make relatively severe bends without fracturing the work metal. However, as metal thickness increases, the amount of forming that can be done on pretempered steel decreases rapidly.

Moderately severe forming can be done on cold-rolled stock that has not been quenched and tempered and on high-carbon steel that has been spheroidize-annealed. Such materials are usually hardened and tempered after forming to improve spring properties. Table 4 shows the effect of the carbon content of steel on bendability and demonstrates the major importance of sheet thickness.

## Formability of Steels

Formability is the ability of sheet metal to be deformed into a desired shape while maintaining structural integrity without tearing, buckling and wrinkling, excessive thinning, and so on. Formability depends greatly on the nature of the forming operation, and various criteria of formability have been developed, depending on the nature of the forming operation and the applied forces (which may be tensile, compressive, bending, shearing, or various combinations of these).

Forming applications may range from simple bending to stamping and deep drawing of complex shapes. Appreciable stretching of the metal also may occur in some operations. The emphasis of this article is on the pressworking of carbon steels, where presses are employed with sets of tools to produce sheet metal products or stampings. This includes press forming, press bending, and press-brake forming. However, this section also addresses formability of sheet steel in drawing and stretch-forming operations, with additional information given in the articles "Deep Drawing" and "Stretch Forming" in this Volume.

In general, one key aspect of formability is the distribution of strain during forming and the evaluation of mechanical properties in terms

of the following (determined from tensile testing):

- Strain-hardening exponent ( $n$ )
- Strain-rate sensitivity factor ( $m$ )
- Plastic-strain ratio, or normal anisotropy factor ( $r$ , or  $r_m$ )

These three properties are used to evaluate the behavior of strain distribution under various forming conditions, and their relevance depends on the nature of the forming operation. Most sheet forming operations usually involve stretching and some shallow drawing, in which case the product of the strain-hardening exponent ( $n$ ) and the normal anisotropy ( $r$ ) of the sheet has been shown to be a significant parameter. In simple stretching operations, however, a forming limit may be determined by the uniform elongation of the metal as it is related to the strain-hardening exponent,  $n$ . Strain-hardening exponents are listed in Tables 5 through 7 for various steels, along with strength coefficients ( $K$ ) for the power-law relation  $\sigma = Ke^n$ .

The  $r$ -value is a measure of the ability of the material to resist thinning while undergoing width reduction. A high  $r$ -value is the measure of a material with good deep-drawing characteristics. High values of  $n$  and  $m$  lead to good formability in stretching operations, because they promote uniform strain distribution, but they have little effect on drawability. Table 8 lists  $m$ -values for various steels and nonferrous alloys. These and other factors influencing formability are covered in more detail in the article "Formability Testing of Sheet Metals" in this Volume.

## Bendability

Bendability commonly is defined as the minimum bend radius,  $R$  (measured to the inner surface of the bent part), to which a sheet metal can be bent without cracking of its outer surface. It is usually given as the minimum  $R/T$  ratio, where  $T$  is the sheet thickness. The minimum  $R/T$

ratio also has been shown to be related to the tensile reduction of the area (RA) of the sheet metal, as obtained from a tension test specimen and cut in the direction of bending.\* This relationship is:

$$\text{Minimum } R/T = (50/RA) - 1$$

This equation has been derived by equating the true strain at which the outer fiber in bending begins to crack to the true fracture strain of the sheet specimen in simple tension, and it is in reasonably good agreement with experimental results (see the section "Bendability" in the article "Bending of Sheet Metal" in this Volume). A curve-fitting modification is also made by increasing the numerator in the equation from 50 to 60 (Fig. 13), which indicates that a sheet with a tensile reduction of area of 60% can be bent completely over itself (hemming) without cracking. However, bendability depends not only on the property of the metal but also on the state of stress (geometric factors) and edge quality, as described in the following sections.

**Factors Affecting Bendability.** Besides ductility of the material, minimum bend radii are affected by angle of bend, length of bend, condition of the cut edge perpendicular to the bend line, and orientation of bend with respect to

\*Because of planar anisotropy of cold rolled sheets (with higher ductility in the rolling direction than in the transverse direction), it is important to prepare the specimens accordingly.

(a) As temperature increases, C decreases and m increases. As strain increases, C increases, and m may increase or decrease. Also, m may become negative within certain ranges of temperature and strain. (b) At a strain rate of  $2 \times 10^{-4} \text{ s}^{-1}$ . Source: Ref 3

direction of rolling. These factors are described subsequently, followed by typical values of minimum bend radii reported for various types of steels.

**Effect of Bend Angle and Length.** Minimum bend radii are larger for a larger angle of bend. Parts in which the length of the bend (direction parallel with the bend axis) exceeds eight times metal thickness have a fairly constant minimum bend radius. When the bend length is less than eight times metal thickness, the bend radius generally must be greater.

**Influence of Stress State.** The effects of notch sensitivity, surface finish of the sheet metal and its lay, and rate of deformation are factors that should be taken into consideration. The beneficial effect of hydrostatic pressure has also been observed in bending. Although specimen size is limited, bending of metals with limited ductility has been carried out successfully in a pressurized chamber, and major increases in bendability have been observed. It has also been shown that as the sheet width-to-thickness ratio increases (thus changing the deformation condition from one of plane stress to plane strain), bendability decreases (Fig. 14).

**Effect of Edge Condition.** Edge condition of the sheet is also significant; the rougher the edge, the greater is the tendency for edge cracking. Bendability thus decreases. When bending low-carbon steel, the condition of the edge perpendicular to the bend axis has little effect on the minimum bend radius. Steels that are susceptible to work hardening or hardening by heating during gas or electric-arc cutting may crack during bending because of edge condition. For these steels, it is often necessary to remove burrs and hardened edge metal in the bend area to prevent fracture. Edges can be prepared for bending by grinding parallel with the surface of the sheet and removing sharp corners in the bend area by radiusing or chamfering.

If the burr side is on the inside of the bend, cracking is less likely to occur during bending. This is important on parts with small bend radii in comparison with the metal thickness and on

parts with metal thickness greater than 1.6 mm ( $1/16$  in.), because fractures are likely to start from stress-raising irregularities in the burr edge if it is on the outside of the bend.

**Effect of Metal Thickness.** Sheet thickness is, of course, a major factor, because minimum bend radii are generally expressed in multiples or fractions of the thickness of the work metal. On parts that require a minimum flange width or a minimum width of flat on the flange, stock thickness will limit both of these dimensions. If

**Fig. 13** Experimental data showing the relationship between bend radius to sheet thickness ratio and the tensile reduction of area for various sheet metals. Source: Ref 3

**Fig. 15** Effect of orientation on bendability

thickness is not critical in the design, the use of thinner stock can make the bending of small radii and narrow flanges feasible.

**Orientation of Bend.** With improved steel-making practices (and the reduction of inclusions), the bend orientation (with respect to the rolling direction of the sheet, Fig. 15) is less critical than in the past. However, it is better to orient a part on the stock so that bends are made across the rolling direction. Sharper bends can be made across than can be made parallel with the rolling direction, without increasing the probability of cracking the work metal. When bends are to be made in two or more directions, the piece can sometimes be oriented in the layout such that none of the bends is parallel with the rolling direction.

In some applications, there is no practical way to avoid making bends parallel with the rolling direction (see example 5 in the section "Lubrication" in this article). A choice must be made in orientation to favor one or another consideration. For example, a blank can be oriented in a strip for economy and the least possible scrap. It can be oriented so that the grain direction will reinforce the metal that receives maximum stress in service. Alternatively, it can be oriented so there is no end-grain runout on a wear surface. In any of

**Fig. 14** The effect of length of bend (strip width) and sheared-edge condition on bend radius to sheet thickness ratio for 7075 aluminum. Source: Ref 3

these cases, orientation may not be optimal for bending.

**Minimum Bend Radii of Steels.** As noted, the minimum bend radii correlates with the ductility (elongation or reduction of area) determined from tensile test. Typical values of minimum bend radii are listed in Table 9 for various materials. Table 10 lists minimum bend radii for 1008 or 1010 hot- and cold-rolled steel sheet in various conditions. The quality of steel has a major influence on the minimum bend radius, especially for hot-rolled steel (Table 10). Table 11 indicates typical commercial-quality steels suitable for 90 and 180° bends.

The types of bends suitable for different hardness levels (tempers) of cold-rolled carbon steel strip are illustrated in Fig. 16. Steel in the higher tempers (low hardness and high ductility) can be bent 180° to a sharp radius without cracks or tears. Bend radii may be smaller for bends made across the rolling direction than for bends made parallel to it. Full-hard strip (84 HRB min) is not recommended for bending, except to large radii. Half-hard tempers (70 to 85 HRB) can be bent 90° over a radius equal to strip thickness, perpendicular to the rolling direction. Quarter-hard tempers (60 to 75 HRB) can be bent 90° over a radius equal to strip thickness, parallel to the rolling direction; it can also be bent 180° around a strip of the same thickness when the bend is perpendicular to the rolling direction.

**Table 9 Minimum bend radii for various materials at room temperature**

Material	Condition(a)	
	Soft	Hard
Aluminum alloys	0	6t
Beryllium copper	0	4t
Brass, low-leaded	0	2t
Magnesium	5t	13t
Steels		
Austenitic stainless	0.5t	6t
Low-carbon, low-alloy, and HSLA(b)	0.5t	4t
Titanium	0.7t	3t
Titanium alloys	2.6t	4t

(a) t, sheet thickness. (b) HSLA, high-strength low-alloy

**Table 11 Suitability of commercial-quality low-carbon steel sheet for bending**

Class and hardness of steel, and bending conditions	90° bends		180° bends	
Cold-rolled steel up to 1.6 mm (0.062 in.) thick				
Suitable commercial-quality steels	1008 or 1010, rimmed, temper passed		1008 or 1010, rimmed, annealed	
Maximum HRB hardness	80(a)		65	
Minimum bend radius	1t		0.25 mm (0.01 in.)	
Hot-rolled steel up to 6.4 mm (0.250 in.) thick				
Suitable commercial-quality steels(b)	1008, 1010	Up to 1030	1008, 1010	Up to 1015
Maximum HRB hardness(c)	68	80	68	72
Minimum bend radius				
Sheet up to 2.3 mm (0.090 in.) thick	3/4t	1½t	1t	1½t
Sheet 2.3–6.4 mm (0.090–0.250 in.) thick	1t	2t	1½t	2t

(a) For 90° bends made across the direction of rolling. The acceptable maximum hardness for 90° bends parallel with the direction of rolling is 70 HRB. (b) Rimmed or capped. (c) Can be met on hot-rolled unpickled steel or steel pickled in sheet form. Hardness values will be higher on mill-pickled hot-rolled coil. With higher hardness values, somewhat larger bend radii will sometimes be required.

Skin-rolled (65 HRB max) steel and dead-soft carbon steel (55 HRB max) steel can be bent 180° flat on itself in any direction.

Table 12 shows the effect of carbon content of some grades of carbon steel strip and sheet on bend radius in standard bend tests. Bend radii for higher-carbon steels and two low-alloy steels are given in Table 4. Low-carbon steel sheet also includes various types of higher-strength steels, which may include carbon steels with some manganese or microalloying. This includes various types of HSLA steels, such as those in SAE J410c. Bend radii are listed in Table 13. Examples of bend radii for cold-rolled and hot-rolled HSLA steel are given in Tables 14 and 15, respectively. Table 16 lists bend radii for a sheet steel with inclusion shape control.

### Formability Diagrams

Sheet metal formability under biaxial stresses is evaluated with the construction of forming-limit diagrams (see the article “Formability Testing of Sheet Metals” in this Volume). By observing and recording strain along both the

major and minor axes of sheet deformation, it is possible to more accurately identify the region of maximum deformation (which would eventually lead to thinning and tearing). Major strains are always positive, because the sheet forming operation always involves some stretching (hence positive strain) in at least one direction. Minor strains may be positive or negative (Fig. 17). The broken straight lines show the states of strain in Fig. 17. The pure shear line indicates that the tensile and compressive strains on the sheet are equal (therefore, the negative 45° slope). The simple tension line indicates a slope that relates to Poisson's ratio in plastic deformation (i.e., 0.5). The vertical line shows the plane-strain condition, where there is no width change (minor strain is zero) as the sheet is stretched over the punch. Finally, the 45° line on the right side of the diagram indicates equal biaxial tension, meaning the major and the minor strains are both tensile and equal.

**Fig. 16** The most severe bend that can be tolerated by each of the standard tempers of cold-rolled carbon steel strip. Stock of No. 1 (hard) temper is sometimes used for bending to large radii; each lot should be checked for suitability, unless furnished for specified end use by prior agreement. Hardnesses shown are for steel containing 0.25% C (max) in the three hardest tempers and 0.15% C (max) in the No. 4 and 5 tempers. Hardness for No. 1 temper applies to thicknesses of 1.8 mm (0.070 in.) and greater; for thinner sheet, hardness would be a minimum of 90 HRB.

**Table 12 Bending limits for hot-rolled commercial-quality carbon steel strip and cold- or hot-rolled carbon steel sheet**

If greater ductility is needed, drawing-quality or physical-quality steel can be used.

Carbon, %	Bending limit
0.15 or less	180° bend flat on itself, in any direction
0.15–0.25	180° bend around one thickness of the material, in any direction

Because of volume constancy in plastic deformation, the thickness change in a particular location can also be calculated by comparing the surface areas of the original and distorted circles. If the area of the ellipse is larger than the area of the original circle, the sheet has undergone thinning. If the areas are the same, there is no thickness change. It is thus possible to predict thinning and tearing of the sheet by observing the shape changes of the original circles during forming (see the article "Troubleshooting Formability Problems Using Strain Analysis" in this Volume).

As expected, friction between the punch and the sheet affects the test results; hence, lubrication of the punch-sheet interface is an important parameter. As for the effect of sheet thickness, experimental results indicate that the boundaries in Fig. 17 rise with increasing sheet thickness; that is, the safe zone is expanded. Also note

that the left side of the forming-limit diagram has a larger safe zone than the right side, indicating the desirability of encouraging the development of a compressive strain during the forming of the sheet. This phenomenon has been used successfully in practice, such as in bulging of tubular workpieces or bending of tubes by applying a compressive force through the axis of the tube.

Experimentally derived forming-limit curves for various steels are given in Fig. 18 to 20. The experimental process of developing forming-limit curves is labor-intensive, and so there is interest to develop computer-based models of formability and/or to develop techniques of deriving formability limits from tensile-test data. For example, Ref 6 describes prediction of forming-limit curves from a single limit yield stress obtained from tensile testing. Hill's anisotropic yield criteria are used to obtain a continuous limit yield locus, which can be termed as forming-limit stress curve. The methodology was tested using literature data on some deep-drawing-quality low-carbon steels, with a band of results shown in Fig. 21. Tensile tests also were conducted on sheet specimens of brass that were selected in three important directions with reference to the original sheet rolling direction. The mechanical properties indicated a significant variation in the three different directions.

### Drawability

Drawability of a metal depends on two factors: the ability of the material in the flange region to flow easily in the plane of the sheet under shear, and the ability of the sidewall material to resist deformation in the thickness direction. Taking

both of these factors into account, it is desirable in drawing operations to maximize material flow in the plane of the sheet and to maximize resistance to material flow in a direction perpendicular to the plane of the sheet. Low flow strength in the plane of the sheet is of little value if the work material also has low flow strength in the thickness direction.

The flow strength of sheet metal in the thickness direction is difficult to measure, but the plastic-strain ratio  $r$  compares strengths in the plane and thickness direction by determining true strains in these directions in a tension test. As noted, a high  $r$ -value is the measure of a material with good deep-drawing characteristics. Rather than average  $r$  over a plane, another way to examine the effect of planar anisotropy is by  $\Delta r$ , which indicates the variation in  $r$  with direction in the plane of the sheet. For values of  $\Delta r$  less than or greater than 1, nonuniform straining during deep drawing will occur in directions parallel and normal to the rolling direction, resulting in the formation of ears.

**Earing** in deep-drawn parts is related to planar anisotropy (i.e., the sheet metal is stronger in one direction than another). This causes ears to form on the drawn part even when a circular blank is used. Ears are shown in Fig. 22(a), while 22(b) shows the orientation dependence on the ears with rolling direction for positive and negative  $\Delta r$ -values. It is important for the process designer to know whether or not the sheet metal is subject to earing, because an extra step is needed to trim away the ears.

### Effects of Alloying

Low-carbon sheet steels are generally preferred for forming. These steels typically contain less than 0.10% C and less than 1% total intentional and residual alloying elements. The amount of manganese, the principal alloying addition, normally ranges from 0.15 to 0.35%. Controlled amounts of silicon, niobium, titanium, or aluminum may be added either as deoxidizers or to develop certain properties. Residual elements, such as sulfur, chromium, nickel, molybdenum, copper, nitrogen, and phosphorus, are usually limited as much as possible. In steelmaking shops, these amounts are based on the quality of sheet being produced. Alloy sheet steels (including high-strength low-alloy grades), however, contain specified amounts of one or more of these elements.

**Table 13 Minimum bend radii for cold bending of SAE 410c high-strength low-alloy steel sheet, strip, and plate**

SAE grade	Ratio of bend radius to material thickness of:		
	To 4.57 mm (0.180 in.)	4.60–6.35 mm (0.181–0.250 in.)	6.38–12.7 mm (0.251–0.500 in.)

0.26C, 1.50Mn	520	75	415	60	18	2 <i>t</i>	3 <i>t</i>	3½ <i>t</i>

(a) Maximum of 0.4 wt% P and 0.05 wt% S; minimum of 0.005 wt% Nb and 0.01 wt% V. (b) Thicknesses above 13 mm ( $1/2$  in.) should be hot formed.

**Carbon** content is particularly significant in steels that are intended for complex forming applications. An increase in the carbon content of steel increases the strength of the steel and reduces its formability. These effects are caused by the formation of carbide particles in the ferrite matrix and by the resulting small grain size. The amount of carbon in steel sheet is generally limited to 0.10% or less to maximize the formability of the sheet.

**Manganese** enhances the hot working characteristics of the steel and facilitates the development of the desired grain size. Some manganese is also necessary to neutralize the detrimental effects of sulfur, particularly for hot workability. Typical manganese contents for low-carbon steel sheet range from 0.15 to 0.35%; manganese contents up to 2.0% may be specified in high-strength low-alloy steels. When the sulfur content of the steel is very low, the manganese content also can be low, which allows the steel to be processed to develop high *r*-values.

**Phosphorus and sulfur** are considered undesirable in steel sheet intended for forming,

**Table 16 Specified bend test radii for inclusion-shape-controlled ASTM A 715 steel sheet**

Grade	Bend test radius for:	
	Transverse bends(a)	Longitudinal bends(a)
50	0.5 <i>t</i>	0
60	0.5 <i>t</i>	0
70	0.75 <i>t</i>	0.5 <i>t</i>
80	0.75 <i>t</i>	0.5 <i>t</i>

(a) For sheet thicknesses (*t*) up to 5.84 mm (0.2299 in.)

drawing, or bending because their presence increases the likelihood of cracking or splitting. Allowable levels of phosphorus and sulfur depend on the desired quality level. For example, commercial-quality cold-rolled sheet must contain less than 0.035% P and 0.040% S. For more applications, phosphorus may be added to the steel to increase the strength. Sulfur usually appears as manganese sulfide stringers in the microstructure. These stringers can promote splitting, particularly whenever an unrestrained edge is deformed.

**Silicon** content in low-carbon steel varies according to the deoxidation practice employed during production. In rimmed steels (so called because of the rimming action caused by outgassing during solidification from the molten state), the silicon content is generally less than 0.10%. When silicon rather than aluminum is

used to kill the rimming action, the silicon content may be as high as 0.40%. Silicon may cause silicate inclusions, which increase the likelihood of cracking during bending. Silicon also increases the strength of the steel and thus decreases its formability.

**Chromium, nickel, molybdenum, vanadium,** and other alloying elements are present in low-carbon steel only as residual elements. With proper scrap selection and control of steelmaking operations, these elements are generally held to

3	0.244	521	76	1.65

**Fig. 21** Comparison of Keeler-Goodwin forming-limit band with a predicted band by Rao and Emani (Ref 6) from tensile-test data of selected low-carbon steels. Tensile properties of steels are given in the table.

minimum amounts. Each of these elements increases the strength and decreases the formability of steel sheet. High-strength low-alloy steels may contain specified amounts of one or more of these elements.

**Copper** is generally considered an innocuous residual element in steel sheet. The strengthening effect of copper is almost negligible in typical residual amounts of less than 0.10%. However, copper is added to steel in amounts exceeding 0.20% to improve resistance to atmospheric corrosion.

**Niobium** strengthens high-strength low-alloy steel through the formation of niobium carbides and nitrides. It can also be used either alone or in combination with titanium to develop high  $r$ -values in interstitial-free steels. These alloying elements remove the interstitial elements carbon and nitrogen from solid solution. Consequently, the steel shows no yield-point elongation.

**Titanium** is a strong carbide and nitride former. It helps develop high  $r$ -values and eliminates yield-point elongation and the aging of cold-rolled annealed steel sheet. Titanium streaks may be a problem in some grades, especially in the form of surface defects in exposed applications.

**Aluminum** is added to steel to kill the rimming action and thus produce a very clean steel

known as an aluminum-killed, or special-killed, steel. Aluminum combines with both the oxygen and nitrogen to stop the outgassing of the molten steel when it is added to the ladle or mold. Aluminum also aids the development of preferred grain orientations to attain high  $r$ -values in cold-rolled and annealed steel sheet. Elongated grains of an approximate ASTM 7 size are found in most well-processed aluminum-killed steels. Because the aluminum combines with the nitrogen, the steel is not subject to strain aging.

**Nitrogen** can significantly strengthen low-carbon steel. It also causes strain aging of the steel. The effects of nitrogen can be controlled by deoxidizing the melt with aluminum.

**Cerium and other rare earth elements** may be added to steel to change the shape of manganese sulfide inclusions from being needle-like or ribbonlike to being globular. Globular inclusions reduce the likelihood of cracking if the sheet is formed without restraining the edges.

**Oxygen** content of molten steel determines its solidification characteristics in the ingot. Excessive amounts of oxygen impede nitride formation and thus negate the effects of alloying elements added to minimize strain aging. Deoxidizers such as silicon, aluminum, and titanium will control the oxygen content. When oxygen combines with these deoxidants, com-

plex nonmetallics are formed. Although most nonmetallics dissolve in the slag, some may become trapped in the steel, causing the surface defects of seams and slivers.

## Effects on Formability

This section describes some key factors that affect the formability of steels in terms of steelmaking practices, surface finish, and metal thickness. From the standpoint of formability, an ideal material should:

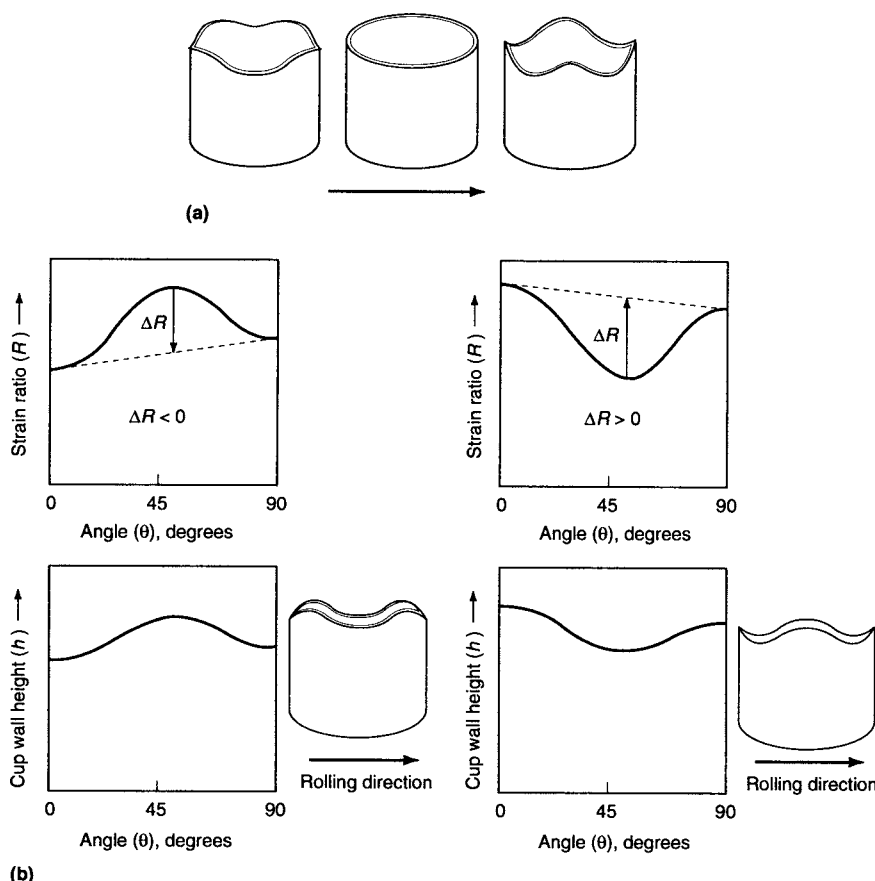

- Distribute the strain in the sheet uniformly (high  $m$ )
- Achieve high strain levels without necking or fracture (high  $n$ )
- Withstand in-plane compressive stresses without wrinkling
- Withstand in-plane shear stresses without fracturing
- Retain part shape on removal from the die
- Retain a smooth surface and resist surface damage

For tentative severity classification of a part, steel near maximum in hardness and near minimum in formability may help identify problems during computer modeling and tool development and tryout runs. Tools developed with steel of below-average quality are seldom troublesome and run with minimum tool breakage and steel rejection when the production run begins. They are also less sensitive to pressure adjustments, variations in sheet thickness, or normal variations in steel properties, and maintenance costs are usually less. Conversely, tools developed with steel of above-average quality are often unsatisfactory when forming regular production shipments of steel.

## Effects of Steelmaking Practices

The formability of steel sheet is determined to a great extent by the steelmaking practices employed in manufacturing. The user of steel sheet normally specifies certain characteristics for the sheet, thus ensuring that the material can be formed in a predictable manner. Adherence to these specifications also implies that the producer of the sheet has observed whatever steel-making practices are necessary to enable the product to perform as indicated. The user can specify either hot-rolled or cold-rolled sheet, and he must select an appropriate quality designation.

**Rimmed steels** refer to the relatively pure iron layer on the surface of the ingot caused by outgassing during solidification. As previously noted, rimmed (or capped) ingot cast steel has been largely replaced by continuous casting, which is more suited to the production of killed (deoxidized) steels. However, rimmed steels may still be available in some circumstances. Rimmed steel generally has a better surface finish than killed steel but is subject to aging.

**Fig. 22** Ear formation. (a) Drawn copper cups showing earing. The rolling direction is indicated by the arrow. Source: Ref 7. (b) The relation of ear formation to the direction of rolling. Source: Ref 8

Rimmed steels have been available as both hot-rolled and cold-rolled products. Hot-rolled commercial-quality rimmed steel is suitable for many forming applications and has the advantage of minimum cost. Cold-rolled, drawing-quality, special-killed, and temper-passed steel has maximum formability and yields parts with the best appearance and finishing characteristics, but it is more expensive. Annealing treatments are used to regain ductility in the product following cold reduction to final thickness. After annealing, rimmed steels must be temper rolled to prevent the formation of Lüders lines during forming.

If rimmed steels are being selected for forming, attention must be paid to deoxidation practice. Killed steel is preferred where sheets must be free of significant changes in mechanical properties (strain aging) for a long time, where neither stretcher strains (Lüders lines) nor roller leveling is permitted, or where better mechanical properties are desired for severe forming applications. Rimmed steels are more suited to stretch-type deformation than to deep drawing, for which aluminum-killed steels are generally recommended. Rimmed steels will age after a period of time following temper rolling. Quality levels of rimmed steel are achieved by controlling chemical composition and annealing practice. Commercial quality is standard, whereas drawing quality is produced under stricter tolerance levels for impurities and is given a longer anneal to ensure uniformity throughout the coil, as well as good formability.

**Strain Aging of Rimmed Steels.** The effect of aging of rimmed steel on formability is difficult to predict on the basis of tests. A certain rimmed steel may not age at all, while another may make the most difficult draws when received and, after aging 30 days, may not make minimum draws.

Strain aging is more pronounced after steel undergoes blanking, forming, or finishing operations. It is therefore advisable to complete the sequence of operations on a part without intervening storage unless artificial aging tests positively indicate the absence of aging.

Artificial aging tests give an approximate measure of the strain-aging characteristics of the steel but do not predict the time at which definite changes in mechanical properties will occur. Artificial aging does not change the tensile strength appreciably; however, yield strength and hardness will always increase, while elongation and uniform elongation will always decrease.

Adding a die operation may reduce the severity of forming enough so that a rimmed steel can be used instead of a killed steel. The overall cost of producing a part is usually the criterion for determining whether to use a more expensive grade of steel or a more expensive die system. Depending on blank size, die complexity, and number of pieces to be produced, the savings in material may offset the additional die costs.

**Stretcher strains**, or Lüders lines, and the Piobert effect, also known as worms, are char-

acteristic markings that appear on the surface of low-carbon steel that has been annealed as a final mill operation. These lines appear during the early stages of stretching and almost disappear as the stretch exceeds 5 to 10%. In tension, the lines are depressions in the surface; in compression, they are raised; and in bending, the same phenomenon causes flutes or kinks. Stretcher strains have no harmful effect on strength. In stampings that are visible in service, stretcher strains are generally unacceptable, because they show clearly through paint.

Stretcher strains can be avoided by a temper pass of approximately 1% cold reduction after final annealing. The correction is normally permanent in killed steel, but stretcher strains frequently recur in rimmed steel unless it is formed in 1 week or less, depending on the amount of temper pass, the temperature, steelmaking practice, and the amount of forming in the stamping.

The probability of stretcher straining can be eliminated from temper-passed rimmed steel and from insufficiently temper-passed killed steel by roller leveling through a machine that flexes the sheet sufficiently in bending to remove the sharp yield point and the yield-point elongation that cause stretcher strains. This amount of cold work does not reduce drawing quality (in some steels, the quality may be improved by reducing the yield point), but additional strain aging is induced, which reduces formability if the steel is stored after roller leveling. Roller-leveled steel should be used within 24 to 72 h after leveling. The sheet should be passed through the roller leveler once in each direction, because approximately 455 mm (18 in.) of the entering end of the sheet is not flexed.

Occasionally, a lift, or even a shipment, of steel does not respond to roller leveling. If such material is unsatisfactory after two passes through the roller leveler, it should not be used for parts that will be exposed in service. However, the performance of annealed steel used for a very difficult unexposed part can be improved by a single pass through the roller leveler.

Annealed sheet cannot be roller leveled for an exposed part, because the flex roll kinks the sheet so severely that, after forming, the deformation will not disappear. In addition, small stretcher strains will occur between the kinks.

Coil breaks and stickers have the appearance of stretcher strains, but both are distinctly different. Coil breaks are regularly spaced, and stickers are spotty. Roller leveling has no effect on these defects.

**Killed Steel.** Generally, killed steel has mechanical properties that are superior to those of drawing-quality rimmed steel (particularly, it has low yield point); killed steel also has better formability and performance, less tendency to form buckles, and is usually free from aging. However, inferior surface properties and more surface defects can be expected from killed steel than from rimmed steel, with consequent higher scrap or repair loss because of these defects. In addition, panels produced from killed steel are

usually less resistant to handling damage and oil canning, because of the lower yield strength of this steel.

Most major producers of stampings restrict the use of killed steel to the most severe draws, to low-volume parts when the steel inventory cannot be used before aging begins in rimmed steel, and to small or irregularly shaped parts for which sheet cannot be roller leveled successfully. To ensure optimal performance, killed steel should have a fine, flat, elongated grain; ASTM grain size 7 to 8 is preferred. Stretcher strains may often be removed by roller leveling if the size and shape of the blank permit. However, this is the responsibility of the supplier, because killed steel is expected to be usable without roller leveling.

**Aluminum-killed steels** are deoxidized with aluminum and, possibly, with silicon. As already mentioned, use of aluminum results in a very clean steel, known as aluminum-killed or drawing-quality special-killed steel. Exceptional resistance to thinning through the sheet thickness (as measured by the plastic-strain ratio,  $r$ ) can be developed through the controlled processing of these steels. Because the pure iron skin characteristic of rimmed steel does not exist in aluminum-killed steel, surface imperfections may occasionally be encountered on aluminum-killed sheet. Both class 1 and class 2 drawing-quality aluminum-killed steels are produced. It should be noted that some aluminum-killed steels that cannot meet the formability requirements for drawing-quality sheet are sold as commercial-quality steel.

**Hot-Rolled Steel.** In the as-hot-rolled condition, the steel has a dark-gray oxide coating on its surface, which offers limited corrosion protection as long as it is undisturbed. However, the oxide flakes off during forming and may be undesirable around the press. Because the oxide coating also interferes with steel surface lubricants, it should be removed before the final finishing of most formed parts. Hot-rolled steel may be ordered pickled (using either hot sulfuric or hydrochloric acid to remove the oxide) and oiled to inhibit in-transit rusting. Rimmed hot-rolled steel in the as-pickled condition will show stretcher strains or Lüders lines on the surface after forming. Whenever surface appearance is important, the steel should be ordered with a temper-rolled surface (skin pass of less than 2% cold reduction) to reduce this tendency. If aging is a problem because of storage requirements, special-killed hot-rolled steel should be ordered.

There is no preferred grain orientation providing high  $r$ -values in hot-rolled steel, but improved grain size and resistance to longitudinal splitting may be attained by closely controlling chemical composition, which differs between commercial- and drawing-quality hot-rolled steel. Higher strength levels (when necessary for the part being formed) are obtained by alloy additions and processing controls to develop improved structure. Because higher strength is associated with forming problems

such as lower ductility, increased springback, and longitudinal bend failures, only high-strength low-alloy steels designed for improved formability should be used in structural parts made by press operations. Mechanical properties of several types of hot-rolled sheet are given in Table 17.

**Cold-rolled steel** sheet forming is produced by the cold reduction of hot-rolled pickled coils, followed by annealing and possibly additional processing, such as temper rolling. Class 1 (E, exposed) should be ordered when a controlled surface finish is required. Class 2 (U, unexposed) is intended for applications in which surface appearance is not of primary importance. Both classes are available as commercial-quality, drawing-quality, or drawing-quality special-killed cold-rolled steel. Mechanical properties of cold-rolled steel sheet are given in Table 18.

Cold-rolled steels in the as-annealed condition may exhibit Lüders lines or stretcher strains from yield-point elongation, if the steel is subject to aging or is not properly killed. The yield-point elongation may be removed by temper rolling the annealed coils. Because temper coiling strengthens the steel and reduces its ductility, it is usually limited to 0.5 to 1.5% elongation of the strip. Temper rolling under tension is more effective than flex rolling or roller leveling for eliminating yield-point elongation, because the steel is more uniformly strained through the thickness. These latter methods are sometimes used in the plants of fabricators because the equipment is less expensive and because it permits the use of aged coils of rimmed steels that may show strain on the surface of formed parts.

In addition to many as-processed surface finishes, cold-rolled sheet may be ordered with a metallic coating that provides corrosion protection or a decorative finish that reduces the manufacturing costs of parts such as appliances or building panels.

**Interstitial-free steel** is vacuum degassed to reduce the amounts of the interstitial elements carbon, nitrogen, and oxygen. It is usually processed to achieve high  $r$ -values ( $r_m \sim 2.00$ ). This type of steel is not subject to strain aging at any stage of processing or manufacture; it exhibits no yield-point elongation. Interstitial-free steel can withstand deeper draws with less breakage than other grades of steel sheet, and coated products made from it generally retain excellent formability.

### Effect of Surface Finish

The surface roughness of sheet steel has an effect on the finishing cost and the appearance of the formed product as well as on processing in dies and on other operations. Dull or slightly roughened surfaces are used especially in parts with the deepest draws in order to retain lubricant through the operations for minimum scoring of the dies and for better flow of metal over pressure pads. Sheet with a surface roughness of approximately 0.75 to 1.3  $\mu\text{m}$  (30 to 50  $\mu\text{in.}$ ) draws well and is smooth enough for most painted parts, such as hood tops and fenders, which require average paint finish.

The need for uniformity among parts that must have matching surface finishes (such as automobile fenders and hoods), even when made from different materials, often dictates the sheet finish. A surface roughness of 0.8 to 1.5  $\mu\text{m}$  (30 to 60  $\mu\text{in.}$ ) for average peak height and two to six peaks per millimeter is considered standard for cold-rolled steel sheet. The surface finish is determined by the finish applied to the cold-mill rolls and the temper-mill rolls. Roll finishes are obtained by shot blasting or electroetching a ground roll surface so that the roll is roughened sufficiently to transfer the pattern to the sheet. As these rolls are used, their finish tends to become smoother; there may be a consequent change in appearance among coils, and press

performance may vary slightly. A rougher sheet surface tends to hold lubricant better and resists galling and cold welding to die surfaces during forming. For parts requiring little forming, a smoother and often preferred finish can be attained when roughness is minimized.

Single-dip or painted parts intended for trim and interior moldings require a smoother surface of approximately 0.25 to 0.5  $\mu\text{m}$  (10 to 20  $\mu\text{in.}$ ). Sheet for average decorative chromium-plated parts should have surface roughness no greater than 0.25  $\mu\text{m}$  (10  $\mu\text{in.}$ ) where the surface is to have no preparation except a light polishing to remove die marks. Parts with surface roughness as high as 0.4  $\mu\text{m}$  (15  $\mu\text{in.}$ ) require additional surface preparation, for example, buffed copper plate applied before another plating.

The selection of fine-grain steel (ASTM grain size of 9) with minimum surface roughness for forming usually sacrifices some ductility and latitude in die design. With fine grain, the steel will be somewhat harder, higher in yield point and elastic ratio (yield point/tensile strength), lower in elongation and uniform elongation, and more likely to strain age.

Surface defects in unexposed parts may be acceptable if the function or the strength of the part is not affected. The following example describes the use of two different grades of steel for forming a concealed panel on which surface defects were acceptable and for forming a panel that required a smooth surface for painting.

### Example 6: Effect of Grade of Steel on Surface Finish of Severely Formed Parts.

Figure 23 shows an inner panel for a glove-compartment door that was made of 0.81 mm (0.032 in.) thick cold-rolled drawing-quality rimmed 1008 steel. On some parts, stretcher strains appeared in the severely stretched flat surface, as shown in Fig. 23. When the stock strained, the parts were used for a part number where the surface was covered by another detail. Parts that had severe stretcher

(a) HRC

strains also cracked in the areas shown in Fig. 23 and were not acceptable.

The outer panel for the same door, however, was visible and had to have a maximum surface roughness of  $1.15\text{ }\mu\text{m}$  ( $45\text{ }\mu\text{in.}$ ) before it was painted. Killed or flex-rolled steel strip was used for the outer panel to minimize the stretcher strains.

The transfer die for the door panel was set up in a 7 MN (800 tonf) straight-side mechanical press operating at 500 strokes per hour. The die was cleaned after each shift, and it was resharpened after making 40,000 pieces. Lubrication was a chlorinated oil applied to the stock by rollers.

### Effect of Cleaning

The procedure for cleaning steel sheet before forming depends on the type and amount of soil present and on the finish specified for the formed surface. Removing soil before forming improves the surface finish, prevents marking of the formed piece, and prolongs die life. Large particles can be removed by wiping, which allows oil to remain and act as a lubricant. Coil stock can be cleaned by feeding it between wiping pads at the press. Another method is to feed the coil through a vat of emulsion cleaner or a light-duty drawing lubricant before it passes between the wiper pads. This procedure is an economical means of simultaneously removing foreign material and providing lubrication.

Cleaning the steel in this manner normally does not completely remove the smudge from the surface. This condition is generally desirable because the smudge acts as filler in the lubricant. Many parts are formed using only mill oil with its smudge for lubrication. If the smudge must be removed, a rotating brush can be used between the emulsion cleaner and the press to scrub the work metal surfaces.

Scale is often removed by abrasive blasting or pickling before the hot-rolled sheet is formed. Both methods remove the residual lubricant. Workpieces that have been in-process annealed without a protective atmosphere are usually

**Fig. 23** Formed panel on which stretcher strains and cracks sometimes occurred. Some of the strained parts could be used in applications in which they were concealed in service; cracked parts were unacceptable. Dimensions given in inches

cleaned by abrasive blasting before final forming. The need to clean parts after forming is determined by the subsequent operations and by the necessary finish. The necessity for cleaning immediately after forming can be minimized by choosing lubricants that are compatible with welding, painting, plating cycles, and handling.

### Effect of Work Metal Thickness

Thickness variations in sheet steel can cause parts made on the same tooling to be of different shapes. This is because of springback or because the pressure applied is either insufficient or excessive at sharp corners or at sides that are to be held at a predetermined angle.

If the sheet is too thick, a die or roll adjusted to a certain thickness may pinch the steel and localize the stretching, thus causing fracturing; or it may work harden the steel and cause excessive springback in a subsequent operation. Thickness greater than the die clearance may cause undesirable marring of the surface of the part or galling and scoring on the surface of the tools, and, in some cases, it may be the reason for tool breakage.

### Bending

Bending is one of the most common sheet metal forming operations used to form flanges, seams, curls and hems. Figure 24(a) shows the parameters involved in bending of sheet metal. During bending, the outer fibers of the bent metal are in tension, while the inner fibers are in compression (Fig. 24b). The metal undergoes plastic deformation with little change in its thickness. Bendability is typically expressed in terms of minimum bend radii, as previously described in the section "Bendability" in this article.

Bending operations are performed using presses, punches, dies, and fixtures. In addition to simple V-bending and edge bending, the industry employs other bending operations, such as flanging, hemming, seaming, and curling (Fig. 25). Additional bending operations, shown in Fig. 26, include channel bending, U-bending, air bending, offset bending, corrugating, and tube forming (see the articles "Bending of Sheet Metal" and "Press-Brake Forming" in this Volume).

**Fig. 24** Bending. (a) Bending of sheet metal. (b) Tension and compression in bending

Punch presses are used for bending, flanging, and hemming carbon steel when production quantities are large, when close tolerances must be met, or when the parts are relatively small. Press brakes are ordinarily used for small lots, uncritical work, and long parts. As workpiece size increases, the advantages of a punch press diminish.

The punch press is usually more economical, and it is more efficient than the press brake in terms of power requirements for a given force on the ram and number of strokes per unit of time. To estimate the press capacity needed for bending in V-dies, the bending load in tons can be computed from:

$$L = lt^2kS/s$$

where  $L$  is press load (in tons of force),  $l$  is length of bend (parallel to bend axis) (in inches),  $t$  is work metal thickness (in inches),  $k$  is a die-opening factor (varying from 1.2 for a die opening of  $16t$  to 1.33 for a die opening of  $8t$ ),  $S$  is tensile strength of the work metal (in tons of force per square inch), and  $s$  is width of die opening (in inches). For U-dies, the constant  $k$  should be twice the values given previously.

The generally accepted tolerance for dimensions resulting from bending is  $\pm 0.41\text{ mm}$  ( $\pm 0.016\text{ in.}$ ) for metals up to and including  $3.2\text{ mm}$  ( $0.125\text{ in.}$ ) thick. For thicker metals, the tolerance is increased proportionately. As in many other mechanical operations, obtainable tolerances are influenced by design, stock tolerances, blank preparation, and condition of the machine and tooling (e.g., see the section "Dimensional Accuracy" in the article "Press-Brake Forming" in this Volume).

### Bending Dies

Typically, bending dies used in press brakes can generally be used in presses, except that the die design must give more consideration to clearance for removing the finished workpiece, because presses ordinarily are not long and narrow like press brakes. Secondly, presses cycle more rapidly than press brakes, and the shut height is not as easy to change; therefore, fewer pieces are bent in air (see the article "Press-Brake Forming" in this Volume). More frequently, pieces are formed by bottoming the dies. This has the advantage of decreasing springback.

**V-dies** are composed of a V-block for a die and a wedge-shaped punch (Fig. 27a). The width of the opening in the V is ordinarily at least eight times the stock thickness. In bending, the workpiece is laid over the V in the die, and the punch descends to press the workpiece into the V to form the bend.

The included angle of a V-bend can be changed by adjusting the distance that the punch forces the sheet metal into the V-die. When the piece must be overbent (to allow for springback), the angle of the punch is smaller than the included angle on the part. Bottoming the punch

and striking the metal severely at the bend is a means of reducing springback.

In V-die bending of a flange along the edge of a wide sheet, distortion is likely to occur. Most of the sheet overhangs the die and lifts up as bending takes place. If the punch strikes too fast, the workpiece will distort and will have irregular break lines. However, if the press ram is slowed down just before the punch hits the work, distortion is minimized.

For this type of V-die work, presses are available in which the ram advances rapidly, slows down just above the work, proceeds slowly through the bottom of the stroke, and returns rapidly. In addition, there are presses in which the rate of ram advance can be controlled somewhat by the operator.

**Wiping Dies.** Another type of bending die is the wiping die (Fig. 27b), where a pressure pad clamps the workpiece to the die before the punch makes contact. The punch descends and wipes one side of the workpiece over the edge of the die. The bend radius is on the edge of the die. To prevent the wiping action from being too severe, there may be a radius or chamfer on the mating face of the punch. When springback must be compensated for, the die is undercut to permit overbending. The flange metal can be put in slight tension by ironing it between the punch and the die. Sharp bends generally cannot be made in one operation in a wiping die without cracking the metal, because a punch or die with a sharp edge will cut the metal rather than bend it.

**Interchangeable V-Dies.** Figure 28 shows equipment for making various sizes of V-bends in a punch press. Four different sizes of punches can be mounted into the punch holder, which is attached to the press slide. In operation, the groove in the die that gives the needed bend is aligned with the punch, and the die is then fastened to the bolster plate on the press bed. Adjustable side and end stops can be used to position the blanks for bending.

With equipment such as that illustrated in Fig. 28, rectangular boxes in a range of shapes and sizes are often produced more economically

by bending flat blanks into folded-end shapes than by deep drawing. Making folded-end pans by bending in adjustable wing dies and cam dies with interchangeable punches is described in the article "Press Forming of Coated Steel" in this Volume.

**U-Bending Dies.** U-shaped pieces can be bent in a die such as the one shown in Fig. 29. The width of the U is adjustable by means of spacers and by changing the width of the knockout. Punches can be mounted in the press with a holder and can be provided to the proper width and shape to make either a U or a channel shape. Side clearance should be 10% more than stock thickness.

**Rotary-bending dies** (Fig. 30) are used to make bends or twists in bars or strip. These dies use cam action to rotate the workpiece. As shown in Fig. 30, a 90° twist is given to strip metal to make a connecting link. The punch is made in two major parts: a hollow cylinder that is solidly mounted to the ram, and inside it a solid cylinder that is free to rotate. The inner cylinder has a 90° helical cam groove in its cylindrical surface that engages a hardened pin in the outer cylinder.

When the ram descends, a slot in the face of the inner cylinder engages the end of the workpiece. After the inner cylinder bottoms, as the ram continues to move down, the spring compresses, letting the outer cylinder move down over the inner cylinder. The action of the pin in the groove makes the inner cylinder rotate, giving the workpiece a 90° twist.

An auxiliary cam keeps the inner cylinder from rotating back in the return stroke, until it

has cleared the workpiece. Near the top of the stroke, the auxiliary cam is released by a stop, allowing the inner cylinder to return to its starting position.

**Cam-Actuated Flanging Dies.** Horizontal motion is often needed to form, or partially form, a flange on a workpiece. One of the most commonly used methods of producing this motion at right angles to the motion of the main press ram is with an inclined surface, or cam, in the die mechanism.

As shown in Fig. 31, a blankholder contacts the work first and holds it in position. Resiliency, either in the form of pressure pins leading to a die cushion or in the form of a spring, allows the ram to continue to descend. A cam actuates the sliding punch, which either forms or completes the forming of the flange and is then retracted. The blank is placed on the pressure pad, where it is held by punch A and wiped past the cam-actuated sliding punch to form the flange. Near the bottom of the stroke, punch B contacts the cam head, which moves the sliding punch to set the flange to the 10.3 mm (0.406 in.) dimension and a 90° angle. Cam-actuated sliding punches on each side of the forming punch can be used for setting flanges on channel and U-shaped parts.

Cam-actuated dies are often used in combination with other tooling to produce complicated parts. When used in tandem with a progressive die, a cam-actuated die can significantly reduce the number of operations needed to produce a part. A drawer front that originally required nine separate operations (two shearing, two notching, one piercing, one box-forming, and three

**Fig. 29** Adjustable U-bending die for use in a punch press

actuated flanging die) with the incorporation of a cam-actuated die.

**Compound Flanging and Hemming Die.** The compound flanging and hemming die shown in Fig. 32 is unusual in having no horizontal motion of punches or dies. There are two cushions: a spring-loaded hold-down plate

and an air cushion for the die plate. As the ram descends, the hold-down makes first contact, clamping the piece securely to the die. As the ram continues to descend, the springs compress, and the angled flange is formed between the angled face of the bending punch and the die plate.

The angle of the bend is set and slightly coined between the chamfer on the edge of the die plate and the angled face of the punch. At this point, the hold-down plate bottoms against the bending-punch holder, then the air cushion begins to yield, lowering the die plate. The edge of the workpiece bumps the corner of the lower die member and folds up into a hem that is completed between the angled face of the bending punch and the mating face of the lower die member.

**Wing Dies.** Special dies for making U-shaped bends have wings that turn up on each side as the punch descends. These dies are described in the article "Bending and Forming of Tubing" in this Volume.

### Single-Curved Bends

**Bending Cylindrical Parts.** Generally, as the bend radius becomes larger, the allowance for springback must be more generous, because less of the bent metal has been stressed beyond its yield strength. Very large radii cannot be easily formed by ordinary bending but must be stretch formed (see the article "Stretch Forming" in this Volume). For large-radius bends, in which the workpiece is formed to half a circle or more, the bend is often made in several stages, as in the following example.

**Edge bending** is the bending of parts with the bend radius perpendicular to the width rather than to the thickness, as is usually done. It is sometimes possible to save material by producing fairly large blanks in simple rectangular form (square-sheared) and then edge bending them into shape. Finish blanking (trimming) is frequently done after edge bending. The size of the offset radii, the length and depth of the offset, and the location of the offset with respect to the flanges may preclude the edge bending of a rectangular blank. The potential cracking and thinning of the outer edge and the wrinkling of the inner edge make the use of a blanked shape more practical.

**Fig. 30** Rotary-bending die used for 90° twisting of strip metal. Die is shown in closed position; inner cylinder has rotated to give workpiece a 90° twist. The auxiliary cam prevents rotation of the inner cylinder until it is free of workpiece.

**Fig. 31** Cam-actuated single flanging die used for producing a multiflanged part. See text for description of operation. Dimensions given in inches

**Fig. 32** Compound flanging and hemming die without horizontal motion

Before edge bending can be selected in preference to blanking from sheet, it is necessary to consider the effect of cold work from the bending operation on subsequent forming. High breakage during edge bending can eliminate the cost advantage of the savings in material. Another consideration is the higher cost of labor and tooling for edge bending, which can also offset the savings in material. The following example describes edge bending that was done to save material and to strengthen the part.

**Example 7: Edge Bending.** Figure 33 shows a curved-end automotive foot-pedal lever that was produced by edge bending a blank sheared from a bar of hot-rolled 1010 steel. The bar, 6.4 mm ( $1/4$  in.) thick, 60 mm ( $2\frac{3}{8}$  in.) wide, and 368 mm ( $14\frac{1}{2}$  in.) long, was sheared lengthwise to produce two blanks 41 mm ( $1\frac{5}{8}$  in.) wide at one end and 20 mm ( $3/4$  in.) wide at the other. Edge bending resulted in substantial material savings over blanking and also a stronger part.

Each blank was edge bent to a 50 mm (2 in.) radius at the narrow end. Other operations included bending the offset and making the two other bends, piercing the 13 mm ( $1/2$  in.) diameter hole, extruding four weld projections (section A-A, Fig. 33), and trimming the radius on the small end. The cutting and forming sections of the dies were made of air-hardened tool steel.

The stock was cut to length in an 1100 kN (120 tonf) end-wheel press (mainshaft extending front-to-back) operating at 60 strokes per minute. Edge bending, forming, trimming, and piercing were done by separate dies in a 1700 kN (190 tonf) open-back inclinable press at 30 pieces per minute.

**Straight Flanging.** Flange bending (flanging) in a wiping die is similar to the cantilever loading of a beam. To prevent movement during bending, the workpiece is clamped to the die by a pressure pad before the punch contacts the workpiece. The bend axis is parallel with the edge of the die. Flanging dies are often cam actuated, with an accompanying loss of efficiency. Holddown pads must be used, adding further to the press capacity requirement.

Considering all factors, the press capacity for flanging in a wiping die may be up to ten times that for forming a similar length of bend in a V-die with a spacing of at least eight times the thickness of the work metal. In some operations, only single flanges are bent. More often, more than one flange is bent at a time. Dies can be simple V-dies, U-dies, wiping dies, or complex flanging dies, such as shown in Fig. 31.

Even when fairly close tolerances must be held, simple V-dies can be used to make a complex part if production is low. Flanging dies are more expensive than ordinary press-brake dies, but considering the time and labor saved in making simple flanged pieces in flanging dies, they often pay for themselves quickly.

**Hemming** is an operation in which flanges are flattened against the workpiece in  $180^\circ$  bends to make a finished or reinforced edge. If the

flange to be hemmed has been bent somewhat more than  $90^\circ$ , the hemming die can be a simple flat bed or anvil and a simple flat punch. Flanging and hemming can both be done in one press in a compound die, as shown in Fig. 32.

### Bending of Curved Flanges

When a flange has concave curvature, the metal in the flange is in tension, and the flange is called a stretch flange (Fig. 34a). When the curvature is convex, the metal in the flange is in compression, and the flange is called a shrink flange (Fig. 34b). The amount of tension or compression in either type of flange increases from the bend radius to the edge of the flange.

Excessive tension in a concave (stretch) flange causes cracks and tears; excessive compression in the convex (shrink) flange causes wrinkles. Stretch and shrink flanges are commonly formed adjacent to each other, producing a reverse flange (as shown in Fig. 36, example 9). See the section "Blank Size" in the article "Press-Brake Forming" in this Volume for bend allowances when using a flat blank.

**Flanging Limits.** Flange radii, flange width, and angle of bend for curved flanges are primarily limited by the amount of deformation that can be tolerated by the flange edges, which depends on the type, thickness, and hardness of the metal and the method of forming. Greater fineness of detail can be achieved in conventional dies than by rubber-pad forming, because of the limited pressures in rubber-pad forming. However, rubber pads provide a uniform pressure over the entire surface of the workpiece, and they can be used to advantage where conventional dies would shear or tear the material.

The approximate percentage of deformation of the free edge is equal to  $100 [(R_2/R_1) - 1]$ , where  $R_1$  is the edge radius before forming (flat-pattern radius), and  $R_2$  is the edge radius after forming, as shown in Fig. 34. For  $90^\circ$  flanges,  $R_2$  is the same as  $R_m$ . Positive values of percentage of deformation indicate elongation (stretch); negative values indicate compression (shrink).

The permissible limits for the conventional die forming of curved flanges in three common

Fig. 33 Pedal lever that was edge bent to save metal and to increase the strength of the part. Dimensions given in inches

steels 1.0 mm (0.040 in.) thick or more are as follows:

Steel	Stretch, %	Shrink, %
1010	38	10
1020	22	10
8630	17	8

These limits should be reduced slightly for thin stock, particularly for shrink flanges. The limits for stretch flanges can be increased if there is an adjoining shrink flange. The compression in the shrink flange helps to relieve the stress in the stretch flange (and vice versa). In addition, the limits of permissible stretch may be increased by filing or grinding the edges of the blank lengthwise; flanges having a calculated stretch of approximately 100% can be formed by this procedure, as in example 9. Shrink flanges are more easily formed if the motion of the die causes some ironing of the metal in the direction of the edge of the flange.

**Severe Contour Flanging.** In small pieces, when enough press force is available, shrink flanges can be formed with sufficient metal flow that the flanges resemble drawn shapes, without using bend relief. Such severe flanging is shown in the following example.

Fig. 34 Dimensional relationships for three types of stretch and shrink flanges

**Example 8: Severe Contour Flanging of Thick Stock.** The hinge half shown in Fig. 35 was formed in one stroke of an 8000 kN (900 tonf) press. By close control of clearances, it was possible to produce the contour, the sharp inside corner on the bend of the flange, and close matching of the outside planes of the flanges and the edges of the part. The metal was drawing-quality hot-rolled 1010 steel 6.07 mm (0.239 in.) thick.

A slight puckering of the metal at the corners between the flanges and the back indicated the severity of the forming. Relief cutouts were not used in this piece, but because of the severity of the forming, the five holes were pierced after forming to hold the location of the two in-line holes in the flanges within  $\pm 0.25$  mm ( $\pm 0.010$  in.) of the three other holes. This practice is quite different from that described in example 13, in which holes were pierced before the part was flanged, and yet hole locations were held within  $\pm 0.25$  mm ( $\pm 0.010$  in.).

The forming die was made of W1 tool steel and was hardened to 58 to 60 HRC. The die was reconditioned after each production lot of 20,000 to 25,000 pieces. The production rate was 600 hinge halves per hour.

**Edge Grinding.** If they are rough, the edges of stretch flanges may crack or tear at critical points. In the following example, a severe bend was made in a difficult-to-form flange, without cracking, after the rough edges had been ground to smooth the surface.

**Example 9: Use of an Edge-Ground Blank to Minimize Cracking of a Severe Stretch**

**Fig. 35** Hinge half on which flanges were formed flush with adjacent surfaces. Dimensions given in inches

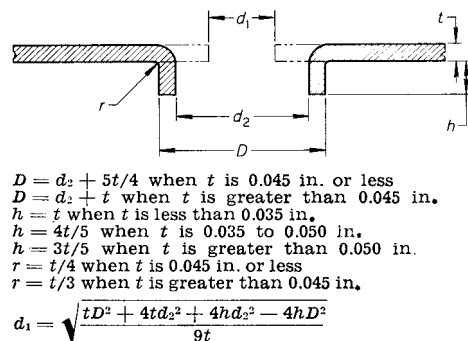

**Fig. 36** Truck-frame cross member that was bent from edge-ground blanks to prevent cracking and tearing of the stretch flanges. Over the length of the two stretch flanges, the 7.9 mm ( $5/16$  in.) inside bend radius was increased, varying to a maximum of 25 mm (1 in.). Dimensions given in inches

**Flange.** The cross member of a truck chassis was made from hot-rolled low-carbon steel that had been pickled and oiled. It was bent from a developed blank into the channel shape shown in Fig. 36. In bending the blank, the edges of the stretch flanges cracked and tore. This problem was solved by filing the edges smooth in the portion of the blank where the stretch and shrink flanges would be formed. Bends were made parallel to the rolling direction.

Because hand filing of the rough edges was costly, grinding was tried, with good results so long as the direction of grinding was along the edge rather than across it. Cross grinding left grooves that increased stress to the same degree as did the original roughness.

Forming was done in a 3800 kN (425 tonf) hydraulic press. The die was a single-action pressure-pad type made of tool steel and had an estimated life of 300,000 pieces. The production rate was two or three channels per minute, in 800-piece production lots.

**Hole Flanging.** Flanges are formed around holes to increase bearing surface or to increase the number or threads that will fit in a tapped hole. A flange formed around a pierced hole is a continuous stretch flange, and Fig. 37 illustrates flange dimensions (in relation to stock thickness, hole size, and flange height) in a particular example for flange holes to be tapped in low-carbon steel. In thick stock, the length of the flange around a hole can be greater than that shown in Fig. 32, but the flange thickness will

**Fig. 37** Dimensions of flanged holes to be tapped, as a function of thickness, for low-carbon steel

**Fig. 38** Swivel washer, with flanged holes, that was made in a progressive die. Dimensions given in inches

taper rather than be relatively uniform. In the following example, flanges were formed around holes that were large compared to the flange width in order to provide a bearing surface.

**Example 10: Swivel Washer with Flanged Holes.** Annealed 1070 spring steel 0.25 mm (0.010 in.) thick was used to make the swivel washer shown in Fig. 38. After forming, the parts were heat treated to 46 to 48 HRC.

The strip layout for the six-station progressive die is also shown in Fig. 38. In the first station, two rectangular holes, one 6.35 mm (0.250 in.) diameter pilot hole, and two 18.0 mm (0.710 in.) diameter holes were pierced. The larger round holes were flanged to 20.3 mm (0.798 in.) in diameter by 1.6 mm ( $1/16$  in.) in depth in the second station. The washer was lanced in the third station and formed in the fifth. The part was cut off in the sixth station. Station 4 was idle.

The die was made of A2 tool steel and was hardened to 60 to 61 HRC. It ran in a 130 kN (15 tonf) open-back inclinable press at 2000 strokes per hour. To maintain a minimum burr height, the die was sharpened after making 60,000 pieces. Total die life was more than 3 million pieces.

### Control of Springback

Springback has little effect in the bending of low-carbon steel. It is considered only when close dimensional control is needed. Springback ordinarily ranges from  $1/2$  to  $1 1/2^\circ$  and can be controlled by overbending or by restriking the bend area. Factors that affect springback include ratio of bend radius to stock thickness, angle of bend (degrees of bend from flat), method of bending (V-bending or wiping), and amount of compression in the bend zone. The amount of springback with a carbon steel and a high-strength low-alloy steel is compared in Fig. 39.

When the bend radius is several times the stock thickness, the metal will need more overbending to stress it beyond the yield point than when the radius is  $2t$  or less. A greater amount of overbending is needed to correct for springback on small bend angles than on large bend angles.

In curved flanges, the radius of curvature and the flange length have an effect on the tension or compression in the flange metal, which in turn affects springback. Springback can vary in a production run of a given part because of variation in stock thickness, variation in stock hardness or temper, tool wear, variation in tool adjustment, and variation in power input (line surges).

**Multiple Bends.** When more than one bend is made in a part, the effect of springback is ordinarily cumulative and may necessitate closer control of the operation than would be needed for just one bend. The following example demonstrates the variation in springback in a part with more than one bend.

**Example 11: Variation in Springback in a Part with Eight Bends.** The part shown in Fig. 40 was produced from 1008 steel in three operations: blank, bend, and trim. In three of the eight bends, springback reduced the 54.74 mm (2.155 in.) dimension, and in five, it increased that dimension.

To find the net magnitude of the springback and how much variation could be expected, 100 random samples were measured from a production lot of 10,000 pieces. As expected, the net effect of the springback was to enlarge the 54.74 mm (2.155 in.) dimension by amounts ranging from 0.64 to 1.52 mm (0.025 to 0.060 in.), as shown in Fig. 40.

The variation in stock thickness was  $\pm 0.05$  mm ( $\pm 0.002$  in.). The inside radius on all bends was equal to stock thickness.

**Restriking and overbending** can be used to set flanges and to offset the effects of springback, as in the following example.

**Example 12: Use of Restriking and Close-Fitting Tools to Control Springback in a Flanged Part.** The column-support bracket shown in Fig. 41 was made of 3.35 mm (0.132 in.) thick drawing-quality cold-rolled 1008 or 1010 steel having a hardness of 48 to 51 HRB. The use of close-fitting punches and dies for certain areas and restriking other areas made it possible to obtain the dimensional accuracy necessary for hole positions, cutouts, and flanges.

All of the round holes were pierced in the flat strip before notching, trimming, punching, and forming. The positions of the small holes with respect to the center were important. The spacing of each set of four small holes was also critical. The flanges along the outer edges had to be uniform in height and set square with the adjacent surface. The open center design and the unbalanced form made it difficult to hold the hole distances and the uniform flange heights.

The forming was done in a progressive die, which was made of O2 tool steel. The cutting punch-to-die clearance was 10% of stock thickness per side. To hold the burr to a minimum height, the die was resharpened after each 50,000 strokes.

The die operated at 400 to 500 strokes per hour. The die was expected to produce parts at this rate for 2 years, and it would then be used for making replacement parts, for which the tolerances were less critical.

### ***Accurate Location and Form of Holes***

Hole position sometimes cannot be held to tolerance when a workpiece is pierced before

bending. When this is so, holes must be pierced after bending, which may require the use of cam-actuated punches, specially shaped dies to support overhanging formed flanges, or punches and dies that are shaped to pierce at an angle.

Holes made before bending are likely to be displaced during bending. Whether or not this displacement can be tolerated must be carefully considered in planning the sequence of operations.

The following example typifies the kind of variation in hole location that can be expected in formed pieces. In this example, if the tolerance on the spacing of the holes had been  $\pm 0.025$  mm ( $\pm 0.001$  in.) instead of  $\pm 0.25$  mm ( $\pm 0.010$  in.), the holes would have been pierced after forming, as they were in example 8.

**Example 13: Variation in Distance between Pierced Holes in a Formed Part.** The bracket shown in Fig. 42 was formed in three operations: blanking and piercing, bending the two small flanges, and bending the two large flanges. The 130.0 mm (5.120 in.) spacing between hole centerlines in opposite flanges had to be held within  $\pm 0.25$  mm ( $\pm 0.010$  in.).

**Fig. 39** Springback of a carbon steel and a high-strength low-alloy steel

**Fig. 40** Variation in flange spacing caused by spring-back in a part with eight bends. Dimensions given in inches

**Fig. 41** Bracket with unbalanced shape that was held within bending tolerances by restriking and by extra-close tolerances on some parts of bending dies. Dimensions given in inches

A reference dimension of 117 mm (4.620 in.) between the inner edges of the holes was computed for the purpose of checking hole spacing with vernier calipers. Caliper measurements of that dimension on 100 randomly selected pieces (from a run of 10,000 pieces) showed variations of  $-0.025$  to  $+0.18$  mm ( $-0.001$  to  $+0.007$  in.) (Fig. 42).

**Free bending** of a workpiece is likely to displace holes from true position and to distort and elongate them. In many press-bent workpieces, this deformation is slight enough to be negligible, but it sometimes causes serious difficulties in assembly or fitting. The likelihood of distortion is minimized when holes are located at least one stock thickness away from the beginning curve of a bend. Other precautions include trapping the hole with a holddown pad that is heavily loaded or relieving the area around the hole with a crescent-shaped cutout. Additional information on the design and protection of pierced holes during subsequent bending is available in the section "Effect of Forming Requirements" in the article "Piercing of Low-Carbon Steel" in this Volume. Examples in that article describe applications in which holes were pierced after bending to avoid hole distortion and displacement during the bending operation.

An instance of acceptable distortion of pierced holes by subsequent bending is described in the section "Piercing Holes at an Angle to the Surface" in the article "Piercing of Low-Carbon Steel" in this Volume. That article also contains other examples on piercing holes before and after bending.

### Accurate Spacing of Flanges

The distance between flanges is another dimension that depends on accuracy of bending. For assembly purposes, this distance may need to be held very closely. Ordinarily, the dimensions at the bases of the flanges are fairly uniform, and variation in the distance between flanges is

**Fig. 42** Variation in distance between centerlines of holes prepierced in opposite flanges of press-bent workpieces. The plotted distances from centerline to centerline were determined by adding 13 mm (0.500 in.) to the gage readings of distances between the inner edges of the holes. Dimensions given in inches

greater near the free edges. If a flanged part is to fit over a mating piece, oversized dimensions may be preferable to undersized dimensions, as in the following example.

**Example 14: Flange Spacing That Was Obtained by Maintaining Tight Gibs and a True Ram.** The bracket shown in Fig. 43 was produced from 5.54 mm (0.218 in.) thick commercial-quality 1010 steel by shearing, blanking, forming, and piercing. The flanges and other bends in the bracket were produced in a five-station transfer die mounted in a 3600 kN (400 tonf) mechanical press. The opposing holes in the flanges were either 16.0/15.9 or 12.8/12.7 mm (0.630/0.626 or 0.505/0.501 in.) in diameter and were pierced after forming. Bend radii were 5.6 mm (0.22 in.). Workmetal hardness was 55 HRB maximum.

For proper fit of the bracket with its mating part, the dimension between the two opposing flanges had to be held between 71.12 and 72.64 mm (2.800 and 2.860 in.); the basic dimension was 71.12 mm (2.800 in.). Figure 43 plots the distance between flanges as measured on 74 pieces during a total production run of 6345 brackets. As these data show, all samples were well within tolerance.

To obtain this degree of accuracy on the heavy-gage bracket, gib clearance in the press was kept between 0.15 and 0.20 mm (0.006 and 0.008 in.), and parallelism of the face of the ram with the top of the bolster was maintained within 0.51 mm (0.020 in.). In addition, before forming, the blanks were checked for thickness, and the forming tool was adjusted to compensate for variations. The dies were made of A2 tool steel and were hardened to 60 to 62 HRC.

### Press Forming

Press forming is a metalworking process in which the workpiece takes the shape imposed by the punch and die. The applied forces may be tensile, compressive, bending, shearing, or various combinations of these. As in bending operations, fabrication may also include various cutting operations, such as blanking, trimming, and piercing. Presses are used to fasten parts together by rivets or by plastically deforming

**Fig. 43** Accuracy of flange spacing obtained by maintenance of small gib clearance and close ram-to-bolster parallelism in press bending of control-arm brackets for passenger-car frames. Dimensions given in inches

mating areas in either or both of the parts. In operations such as staking, folding, crimping, curling, or press assembly, projections of various sizes and shapes are deformed so that the assembly is reasonably strong.

This section describes the accuracy in press forming of steels, effect of workpiece shape, and the press forming of ribs, beads, and bosses. If a part can be made by forming sheet metal in a press, this is ordinarily the least expensive method of manufacture, except when only a few pieces are needed. The low cost per piece results from the high production rates and the efficient use of metal usually obtainable in the press forming of sheet metal. The accuracy inherent in press forming is satisfactory for most requirements. Greater accuracy can be achieved by the use of precision tooling and by maintaining close control over press conditions.

In some applications, the metal requires appreciable stretching in order to retain the shape of the formed part. Speed of forming has little effect on the formability of steels used for simple bending or flanging or for moderate stretching. The maximum velocity of the punch when it contacts the blank in such conventional press forming is usually not greater than approximately 1 m/s (200 ft/min). When local stretching is more than 20%, workpiece movement or flow over the face of the punch or the blankholder may be considerable. The flow of the metal in such operations is controlled by frictional forces, so stretching failures are sensitive to speed. In this case, a maximum punch velocity of 0.2 m/s (40 ft/min) is recommended, although the critical value differs for each steel and die combination. High punch speeds also shorten tool life.

### Accuracy in Press Forming

Tolerances that can be maintained in the press forming of steel depend on press condition, accuracy of the tools, workpiece shape, and hardness and variation in the thickness of the work metal.

**Flange Width.** In forming 90° flanges, if the break lines in the plan view and side elevation are straight or nearly straight, there should be no difficulty in holding a tolerance of  $\pm 0.76$  mm ( $\pm 0.030$  in.) on flange width. When flange break lines are curved significantly, tolerance usually must be increased to  $\pm 1.52$  mm ( $\pm 0.060$  in.).

**The overall length and width** of large formed parts such as automobile hoods and deck lids can usually be held to a tolerance of  $\pm 0.76$  mm ( $\pm 0.030$  in.). For small formed parts, closer tolerances can be met in production.

**Bend Angle.** Tolerances that can be held on bend angles depend greatly on the thickness and hardness of the work metal and on the flange height, because these factors affect springback. A 90° bend in low-carbon steel will spring back approximately 3°; therefore, either the dies are built to overform by this amount or the bend region is compressed to set the corner. To provide enough metal for gripping in the die, the

minimum inside flange height should be two times the stock thickness, plus the bend radius.

**Distance between Holes.** Distances between the centerlines of pierced holes that lie in a common surface of a formed part are commonly held within a total tolerance of 0.25 mm (0.010 in.) or less (see the article "Piercing of Low-Carbon Steel" in this Volume). The relation of hole positions in parallel or in-line surfaces of formed parts can be held to  $\pm 0.38$  mm ( $\pm 0.015$  in.); holes with a smaller tolerance on the centerline distance should be pierced after forming (Fig. 44).

**Distance between Offset Surfaces.** In ordinary commercial practice, the distance between two offset flat surfaces in parallel planes can be maintained within  $\pm 0.38$  mm ( $\pm 0.015$  in.). For closer tolerances, extreme accuracy must be built into the tools, and the stock thickness must be held closer than normal mill tolerances. The following example describes the techniques used to maintain a tolerance of  $\pm 0.25$  mm ( $\pm 0.010$  in.) on the distance between surfaces.

**Example 15: Variation of a Critical Distance between Offset Parallel Planes.** On the brake-assembly backing plate shown in Fig. 40, the distance between the tops of the six pads (A to F, Fig. 45) and the bottom of the center mounting face had to be within  $\pm 0.25$  mm ( $\pm 0.010$  in.). The ranges of dimensions for all six pads as measured on 22 pieces are plotted in the graph in Fig. 45. Of the 132 individual measurements, only 7 exceeded the limits. The spread in dimensions was the result of a combination of variables, including stock thickness ( $\pm 0.18$  mm, or  $\pm 0.007$  in.), springback after forming and coining, and condition of the press.

Springback was unpredictable and varied among different lots of steel. Therefore, the die was made extra rigid, and the inserts for coining the pads (inserts 1 and 3, section B-B, Fig. 45) were made adjustable to compensate for variations in stock thickness. Coining reduced stock thickness at the 1600 mm<sup>2</sup> (2.5 in.<sup>2</sup>) pads to 2 to 2.3 mm (0.080 to 0.090 in.)—a 15% reduction.

**Fig. 44** Tolerances on hole position and distance between offset parallel surfaces on formed parts, and recommended dimensions to be specified for formed offsets. The tolerances shown apply to holes pierced before forming; holes in offset parallel surfaces with position tolerances less than  $\pm 0.38$  mm ( $\pm 0.015$  in.) should be pierced after forming. Dimensions given in inches

The backing plate was made in two operations, both in a 7.1 MN (800 tonf) mechanical knuckle press with a 125 mm (5 in.) stroke, which was operated at 20 strokes per minute. In the first operation, coil stock was fed into a progressive die, where the inner portions of the part were formed, the six pads were partly completed, the center hole was pierced, and the outside diameter was blanked. The outside flange was formed, and the six pads were coined to height and parallelism in a second die (section B-B, Fig. 45).

The press slide was parallel to the bolster within 0.25 mm/m (0.003 in./ft). The slide and the press bed were large enough to keep the die set centered, thus minimizing the possibility of error. The die set had four heavy guideposts in long bushings. The main parts of the punch and die were made of 6145 steel hardened to 45 to 50 HRC and ground after hardening, and the inserts for coining (inserts 1 through 4, section B-B, Fig. 45) were made of O1 tool steel hardened to 60 to 61 HRC and ground.

**Holes Close to a Bend.** Whether a hole that is close to a bend is pierced before or after forming depends on the function of the hole, its closeness to the bend, the bend radius, and the stock thickness. When the distance from the edge of the hole to the inside surface of the other leg of the bend is less than  $1\frac{1}{2}$  times the stock thickness, plus the bend radius, the outer portion of the hole is likely to deform as a result of stretching of the metal. If the deformation is acceptable, the hole can be pierced before forming; otherwise, it must be pierced after forming. When the offset angle on formed parts is unimportant, stating the minimum flat and maximum radius dimensions,

**Fig. 45** Variation of offset distance in a formed and coined backing plate for a brake assembly. Dimensions given in inches

as in Fig. 44, allows the maximum practical tolerance in producing acceptable parts.

**Trimmed edges** can be held to close tolerances when they are trimmed by one punch and when trimming is done after any forming that would cause distortion, as in the following example.

**Example 16: Forming and Accurate Trimming in a Progressive Die.** Figure 46 shows an eggbeater side frame that was produced in a four-station progressive die from 1 mm (0.040 in.) thick cold-rolled 1008 to 1010 steel strip 19 mm ( $\frac{3}{4}$  in.) wide. For accurate fit in assembly, the end of the part was trimmed to the close tolerances indicated in Fig. 46 after the U-shaped bead flanked by the vertical tabs had been formed. The bead was formed by drawing metal from the surrounding area and by stretching.

The stock had a No. 6 edge, a No. 3 finish, and a hardness of 55 to 65 HRB. The No. 6 edge (a square edge produced by edge rolling the natural edge of hot-rolled strip or slit-edge strip) was relatively burr free. Because the edges of the strip were also the edges of the completed part, the use of a No. 6 edge eliminated a deburring operation. The No. 3 finish was particularly suited to bright nickel plating without prior polishing or buffing. Stock was purchased to average in the lower part of the standard thickness range of  $\pm 0.05$  mm ( $\pm 0.002$  in.) and within the standard width tolerance of  $\pm 0.38$  mm ( $\pm 0.015$  in.). The sequence of operations in the four die stations was as follows:

- Lance and form semicircular indent, and notch-trim
- Pierce rectangular slot at one end, pierce round hole, and emboss weld projections
- Lance tabs, form bead, and form flange around round hole
- Cut off (trim) and form contour

**Fig. 46** Eggbeater side frame that was formed and accurately trimmed in a progressive die. Dimensions given in inches

The die, made of D2 tool steel, was used in a 665 kN (75 tonf) press; die life between regrinds was 65,000 pieces. Mineral oil was used as the lubricant. The production rate was 360 pieces per hour; annual production quantity was 600,000 pieces.

**Close Tolerances.** Closer-than-conventional accuracy can be attained in sheet metal parts with accurate dies, precise location of the parts in the dies, and handling equipment designed to avoid damage to semifinished or finished workpieces. Press condition is also an important factor. The following example describes the techniques used for close-tolerance forming in progressive dies.

**Example 17: Use of Progressive Die to Meet Close Tolerances on a Lamp Bracket.** The lamp bracket shown in Fig. 47 had several tolerances that were closer than normal. Three holes had to be pierced to a tolerance of  $+0.13$ ,  $-0$  mm ( $+0.005$ ,  $-0$  in.) on diameter, and two of the holes had to be in line within 0.25 mm (0.010 in.) after forming. In addition, when the  $104^\circ$  bend was made with the pre-formed flanges out, the radius of bend on the flanges had to be held within 0.38 mm (0.015 in.) total indicator reading, and the  $10^\circ$  angle of the flanges had to be held within  $\pm 5^\circ$ . The bracket was produced in a seven-station progressive die with two piloting stations that could have been used for auxiliary operations such as shaving or restriking, if necessary. The operations were as follows:

- Notch for stop, pierce one 10 mm (0.395 in.) hole, pierce two 6.7 mm (0.265 in.) holes
- Blank the contour of the ears
- Pilot
- Blank the partial contour
- Form the two long flanges
- Pilot
- Form the  $104^\circ$  angle and cut off

The material was cold-rolled 1010 steel strip in No. 4 temper. The strip was 2.4 mm (0.095 in.) thick by 86 mm ( $3\frac{3}{8}$  in.) wide. The progressive die was mounted in a 665 kN

**Fig. 47** Lamp bracket that was press formed to close tolerances in a progressive die. Dimensions given in inches

(75 tonf) straight-side mechanical press with a flywheel drive, a 152 mm (6 in.) stroke, and a maximum rate of 60 strokes per minute. The press was equipped with an air clutch. Ball-lock punches, die bushings, and easily reproducible die sections were used throughout.

The die was made of D2 tool steel hardened to 58 to 60 HRC and had a life of 55,000 pieces per regrind. Production was discontinued after 2.5 million lamp brackets had been made.

**Flatness.** The longitudinal and transverse stresses set up during the forming of a part can cause it to warp, particularly if the part is made of steel that is not uniform. Depending on the size and shape of the part, either smooth flattening or embossing can be used to maintain flatness.

**Press Condition.** The accuracy and condition of presses must be maintained within close limits when tolerances on formed parts are critical, regardless of the type of operation. Press slides that are not parallel with the bed at the bottom of the stroke can cause uneven stock thicknesses when the punch bottoms against the die surface. Unbalanced forming forces can shift the punch, producing out-of-tolerance workpieces. In some forming applications, shifting of the punch can be minimized by tipping the workpiece to balance the forces. Heel blocks and other means of positively maintaining the punch-to-die relationship are used to overcome unbalanced forming forces and shifting of the punch slide.

### Workpiece Shape

The size and shape of the workpiece and the number of operations needed to make it must be considered in determining press capacity (both force capacity and bed size) and the type of tooling used. Open-end parts, or parts with one or more open edges, can be formed two or more at a time from a single blank. Sheet metal elbows that cannot be made from tubing are formed four halves at a time, then separated and assembled into two elbows. Small flanged parts with a low ratio of flange width to stock thickness are often difficult to form because of slippage and unbalanced forces. Forming two parts at a time can balance the forces and reduce scrap. More information on the factors that affect press selection is available in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume.

**Recessed parts** require special precautions in forming to avoid wrinkling in the flat area surrounding the recesses and to prevent cracking the corners of the recess. In the forming of a deep recess in a large panel, for example, adjustment of the blankholder pressure may be necessary to prevent such failures. In this application, the deep recess is formed first, with the material being drawn into the recess from the end and two sides of the blank; stretching done in the final forming removes wrinkles.

When the cross section of the recess is a circular arc, acceptable percentages of stretch for

recesses with various height-to-diameter,  $h/d$ , ratios are:

$h/d$ ratio	0.10	0.15	0.20	0.25	0.30
Stretch, %	3	6	10	15	22

**Dish-shaped parts** having only one recess, of regular or irregular shape, are commonly formed by stretching the metal over a punch. The punch nose should be smoothly contoured so as not to trap the metal and should have as large a radius as possible. Parts with a straight sloping surface can be free formed by stretching between a clamp ring and a small-diameter punch. On large parts, stretch is most severe near the punch, and the work metal elongates and drapes from its own weight, forming an undesirable concavity in the wall. Both of these defects, uneven stretch and concavity, can be minimized by using a stepped punch.

**Cone-shaped parts** that are formed by a combined stretch-and-draw operation can be made in a progressive die without first cutting the contour. This reduces the number of die stations that are required, and more than one part can often be formed at a time.

**Shapes with Locked-In Metal.** In the forming of some shapes, metal may become locked-in (formed so that metal flow is stopped) before enough of it has been drawn into the cavity to form the part completely, and the metal sometimes fractures before the punch has reached the bottom of the stroke. In some cases, the strain that causes fracturing can be relieved by piercing a hole or lancing the metal in a non-critical area.

**Severely Formed Shapes.** Developed blanks are sometimes used to provide sufficient metal in critical areas of severely formed parts. Pre-forming helps to distribute the metal before final forming and restriking operations, thus reducing the severity of these operations. Edge condition and ductility greatly influence the success of severe forming.

**Offset Parts (Edge Bending).** Scrap loss can sometimes be reduced when blanks can be produced in simple rectangular form and subsequently edge bent in the final shape. Whether or not the severity of the edge-bending operation will adversely affect subsequent forming operations must be considered. A potential savings of work metal can be quickly lost if edge bending work hardens the pieces to the extent that many are broken in forming. In some applications, the tensile and compressive stresses set up in edge-bent blanks can be counteracted by forming stretch flanges around the inner contours of the bends and compression flanges on the outer contours. The same flanges made on a cut blank instead of an edge-bent blank could fracture during flanging. On the other hand, reverse flanges made on an edge-bent blank may cause more severe stress than they would on a cut blank and may possibly lead to a high scrap rate.

The edge-bending operation and its tooling are an added expense in the fabrication of a part.

This expense must be compared to the savings of work metal when one method is to be selected over the other.

### Large Irregular Shapes

Large parts are usually formed in single-operation or compound dies mounted in large-bed presses. If the part is irregular in shape, care must be taken in shaping the blankholder surfaces, in planning the orientation of the workpiece in the die, and in planning the die operation to obtain approximately even stressing of all areas of the workpiece and to form the piece in the fewest possible operations.

To make shallow draws, sometimes the metal must be locked in place by the blankholder in order to stretch the sheet metal over the punch enough to set the contours. Draw beads or selective local applications of drawing compound are used to restrict and control metal flow.

Large, irregularly shaped parts are often made by preshaping blanks before forming. This method reduces scrap when making the blank and neutralizes the tensile and compressive stresses in the flanges. The blanks for automobile fenders and other parts are preshaped by bending and tack welding them into a cone shape.

**Use of Shaped Blankholders.** Some parts that are made from preformed blanks are formed with the aid of shaped blankholders to avoid distortion of the previously formed contours. In addition, parts that are not completely formed in one operation may have to be clamped in a shaped blankholder in a second-operation die. The part in the following example had a peripheral offset that served as a locating surface in the second-operation die, but the part had to be clamped to prevent distortion during final forming.

**Example 18: Holding a Previously Formed Workpiece in a Shaped Blankholder to Prevent Distortion during Subsequent Forming.** After the first forming operation, the blank for the fan shown in Fig. 48 had a 4.78 mm (0.188 in.) offset outer rim and a 22 mm ( $\frac{7}{8}$  in.) deep recessed inner web. The surfaces were used as locators in a shaped blankholder for the subsequent trimming and forming operations.

Spring-loaded pressure pads were used to hold the rim and the web while the blades were twisted. The pressure pads bottomed at the end of the stroke so that any deformation in the rim or the web could be flattened. The 4.78 mm (0.188 in.) offset was placed over a close-fitting plug to prevent radial distortion of the rim.

Three operations were needed to produce the part. In the first operation, the 4.78 mm (0.188 in.) offset was formed to 471 mm (18.550 in.) in diameter, and the 22 mm ( $\frac{7}{8}$  in.) deep recess was formed at the same time. In the second operation, the 485.7 mm (19.121 in.) outside diameter was trimmed, and the 44.6 mm (1.755 in.) diameter hole and 24 T-shaped cut-outs at 15° spacing were pierced. The T-slots

gave shape to the fan blades prior to twisting at 45°, which was done in the third operation.

The cutting elements in the dies were made of A2 tool steel. The forming dies for the offset rim and recessed web were of low-carbon high-strength alloy cast iron. The blade formers were made of prehardened low-alloy tool steel. The workpiece was made of a 0.89 mm (0.035 in.) thick cold-rolled 1010 steel blank 510 mm (20 in.) square.

**Recesses in Large Panels.** The forming of recesses in large panels at some distance from the edge can be difficult. Because the sheet is large, the recesses appear to be shallow, but forming may actually be severe in terms of localized deformation.

If the recess is fairly small and far enough from the edges of the blank so that there is a large resistance to metal flow, the metal can be overstressed at the punch nose and can fracture or tear. To prevent tearing, blankholder pressure is kept as low as possible to allow almost unrestricted metal flow, but this may produce wrinkles radiating from the lip of the recess. These wrinkles can be removed by stretching the sidewalls of the recess in a second forming operation.

**Large cup-shaped parts** that must be stronger in the bottom surface than in the wall are often designed with tapered wall sections. A tapered section can be made by machining the part before or after drawing.

High-strength low-carbon steels of thinner gage than conventional low-carbon steels can be used without tapering, but they are more difficult

Fig. 48 Large sheet metal fan that was clamped in a shaped blankholder during the second forming operation. Dimensions given in inches

to draw and are more expensive. The use of a tapered blank for a cup-shaped part is described in the following example.

**Example 19: Forming a Large Disk from a Tapered Circular Blank.** The truck-wheel disk illustrated in Fig. 49 was formed from a blank 610 mm (24 in.) in diameter that had been roller tapered from a 500 mm (19 in.) diameter blank with a 90.5 mm ( $3\frac{1}{2}$  in.) diameter center hole. Taper was approximately 0.04 mm/mm (0.04 in./in.) of radius. The material was annealed hot-rolled 1012 or 1015 steel, 9.52 mm (0.375 in.) thick, abrasive blasted to remove scale and oxide.

The blanks were tapered back to back, two at a time, giving each disk only one rolled surface. The tapering rolls were stopped before reaching the edge of the blank, in order to maintain an even taper. Otherwise, lack of resisting stock at the edge would have caused a torn edge. Tapering started at a diameter of 260 mm (10.25 in.), just beyond the circle describing the outer edges of the six round holes; this gave a stock thickness of 8.38 mm (0.330 in.) at the 17.5/12.7 mm (0.69/0.50 in.) radius.

The combined forming and trimming operation was done in a 13.3 MN (1500 tonf) hydraulic press, with the rolled surface of the work face down in the die. The blank was trimmed to 584 mm (23 in.) in diameter in a compound blank-and-draw die at a rate of 375 per hour. The die was made of O1 tool steel and was reworked after making 40,000 pieces.

A second operation sized the 498.2 mm (19.616 in.) outside diameter, enlarged the center hole to  $164.4 \pm 0.05$  mm ( $6.471 \pm 0.002$  in.) in diameter, and pierced six 32.5 mm (1.28 in.) diameter holes, using a 7.1 MN (800 tonf) mechanical press. In the third operation, six hand holes were punched, one at a time. To attach a rim to a disk, 16 rivet holes evenly spaced around the circumference of the flange were pierced in both the disk and the rim at the same time.

The optional 1015 steel had the highest carbon content that could be used in this part. Work hardening increased its strength and hardness. If the hardness of the workpieces exceeded 91 HRB, hairline cracks radiated from the rivet holes, causing rejection, as observed when 1020 steel was used.

Fig. 49 Truck-wheel disk that was formed from a tapered blank. Dimensions given in inches

**Localized severe forming** is encountered in making many large irregular shapes by press forming. This imposes stringent demands on process planning; quality of work metal; lubrication; and the design, material, and maintenance of dies, as demonstrated in the following example.

**Example 20: Severe Embossing and Hole Flanging in Press Forming a Control Arm.** The severe embossing and hole flanging demanded on the automobile control arm shown in Fig. 50 required the use of drawing-quality steel for the workpiece and high-quality tool steel for the dies, close attention to tool maintenance, and the use of a heavy-duty lubricant. The stock was hot-rolled drawing-quality rimmed 1008 or 1010 steel, pickled and oiled, with a hardness of 55 HRB. Commercial-quality steel had been tried but was unsatisfactory for the severe forming. Stock thickness was 3.96 or 4.17 mm (0.156 or 0.164 in.). Wall thickness of the hole flanges had to be at least 2.67 mm (0.105 in.), and flange width was 7.62 mm (0.30 in.). The parts were formed with dies of hardened W2 tool steel. A developed blank was used, making a final trimming operation unnecessary. The operations were as follows:

- Blank to developed outline, pierce two locating holes, form center boss—done in a 1.8 MN (200 tonf) mechanical press with W2 tool steel die inserts hardened to 57 to 60 HRC
- Form in a 5.3 MN (600 tonf) mechanical press using W2 tool steel dies hardened to 61 to 64 HRC
- Pierce two holes in flanges, enlarge one locating hole, pierce oval hole in center boss—done in a 620 kN (70 tonf) inclined-bed mechanical press
- Restrike to size and sharpen radii, form dimple, flange round hole and oval hole in a 5.3 MN (600 tonf) mechanical press

**Fig. 50** Press-formed control arm on which embossing and hole flanging were of near-maximum severity. Dimensions given in inches

- Pierce remaining holes in a 620 kN (70 tonf) inclined-bed mechanical press
- Outward flange two side holes to 35.5/35.4 mm (1.398/1.394 in.) in diameter, 2.67 mm (0.105 in.) minimum wall thickness, and 7.62 mm (0.30 in.) minimum flange height, using hydraulic equipment designed for this part

A dry-film lubricant consisting of soap and borax was applied to the blank. Where further lubrication was needed, an oil-based compound was added. Production rate ranged from 200 to 325 pieces per hour, production-lot size was 10,000 pieces, and annual demand was more than 200,000 pieces. Except for minor repairs, the dies were good for 1 year of production.

**Blanks That Cannot Be Nested.** Irregularly shaped parts frequently must be made from developed blanks with a contour that makes close nesting of the blanks impossible. Channel-shaped parts with flanges or web of varying width use blanks that are cut with more scrap than parts with flanges or web of unvarying width, and an excessive amount of scrap may be generated in producing them.

In some applications, material that would otherwise be wasted can be moved into a useful location after notching or lancing. This was done in the following example, in which the web was notched at the end and then spread into a V-shape to increase flange height at the ends and to reduce blanking scrap.

**Example 21: Use of a Notched Blank to Increase Flange Width and Reduce Scrap in Forming an Irregular Channel-Shaped Part.** A flange of varying width was needed on the channel-shaped truck-frame member shown in Fig. 51. Instead of using a contoured blank, which would have meant considerable waste in blanking, the additional flange width was gained by notching each end of a nearly rectangular blank and spreading the notch into a V-shape during the forming operation. The end of each

**Fig. 51** Press-formed truck-frame member that was notched and spread to increase flange width locally and therefore save material in blanking. Dimensions given in inches

notch was radiused to minimize cracking during forming. The stock saved by notching the blank was 1.4 kg (3 lb) per piece.

The workpiece was made of 4.54 mm (0.179 in.) thick hot-rolled, rimmed 1008 steel, pickled and oiled. Each of the two notches in the blank was 9.1 mm (0.36 in.) wide by 181 mm (7 in.) long. The notches were spread to make V-shaped openings 56.9 mm (2.24 in.) wide at the ends. Flange widths varied from 50 mm (2 in.) at the center of the part to 127 mm (5 in.) at each end of the channel. The operations were:

- Cut blank to developed outline, and pierce large center hole. A 3.1 MN (350 tonf) mechanical press with a mechanical unloader produced 300 to 400 blanks per hour.
- Form completely, including flange around center hole, in a 16 MN (1800 tonf) hydraulic press
- Pierce all holes in the web, and trim 18.8 mm (0.74 in.) radius at two places on each end in a 2.9 MN (325 tonf) mechanical press
- Pierce holes in top and bottom flanges, and restrike flange ends in a 2.9 MN (325 tonf) mechanical press

Presses for the aforementioned second, third, and fourth operations, operating at 250 to 310 strokes per hour, were set up in a line with transfer equipment between them. In the second operation, a spreader was incorporated into the die to assist in opening the notch to a V-shape. The 181 mm (7 in.) length of the notch had been carefully developed so that the notch would spread to the required maximum width without causing the work metal to split. After forming, a 15.87 mm (0.625 in.) diameter hole was pierced at the end of each notch to remove any fractured material or other stress raisers aggravated by the severe edge forming.

The forming punches were made of 1045 steel. The wear surfaces on the punch and die were W2 tool steel hardened to 61 to 64 HRC. As a lubricant, a soap solution was dried on the stock. Some heats of steel were difficult to form; for these, an oil-based compound was used as additional lubricant.

The truck-frame member was made in lots of 27,000 pieces for an annual production of 270,000 pieces. Except for minor repairs, such as replacing small punches, the dies were good for 1 year of production.

**Use of Draw Beads.** A draw bead in a blankholder controls the movement of metal into the die cavity by providing additional resistance to metal flow. Draw-bead geometry and placement have major influence on the strains in sheet forming. The location of the beads is usually determined in die tryout; dies for producing similar parts can be used as a guide. The restraining action must be sufficiently high to provide the force necessary to prevent wrinkling and surface distortions in both the flange and unsupported areas, but not so high to result in excessive thinning or splitting in the sheet metal. Draw bead restraining force is caused, to a large

extent, by deformation resulting from bending and unbending of the sheet metal in the draw bead area, and to a lesser extent, by the frictional forces resulting from the sliding contact between the binder and the sheet metal. The bending force was found to be inversely proportional with the radius of curvature of the bead, whereas the friction force was found to be directly proportional with the coefficient of friction and the binder force.

A single bead is generally placed around the cavity, and additional beads are placed in areas where more control is needed. Conditions may indicate that the bead size should be reduced or that the whole bead omitted in some places. Short beads can be placed at an angle to deflect metal into or away from local areas.

Whether the bead is placed in the draw ring or in the blankholder is determined by the die construction. Placing the groove in the upper member has the advantage that it will not catch dirt. However, the groove should be put in the member that is to be altered during spotting for mating of opposing surfaces. For convenience in making alterations, this is usually the lower member.

Unless they are part of the product design, draw beads are placed outside the trim line, as shown in Fig. 52(a). The trim line can be on the punch or the blankholder. A locking draw bead, such as that shown in Fig. 52(b), is used to provide maximum restriction to metal flow. Locking beads are used when forming to shape is done primarily by stretching the metal under the punch, rather than by moving metal into the cavity.

Figure 52(c) shows the use of conventional and locking beads. Here, conventional beads control metal flow into the die cavity until the last portion of the punch movement, when the locking bead gradually engages the metal to restrict its flow. The last fraction of a millimeter of punch travel causes stretch in the metal under the punch.

Beads in the concave surfaces of a blankholder are usually 3 mm (0.12 in.) deeper than beads on the top or straight surfaces. This eliminates locking on the top surfaces during preforming of the blank to the shape of the concave blankholder surface.

Sometimes, draw beads need not be used for the full depth of draw, or need to be used only in certain locations, such as the corners of regular or irregular polygon-shaped parts. In such cases, some of the material may be allowed to slip through the draw bead to be retained at the end of the stroke only by blankholder pressure. More information on the design and construction of draw beads is available in Ref 9 to 11 and the article "Deep Drawing" in this Volume.

**Use of Flat Binders.** In a flat binder, sheet metal restraining force is caused by the friction force resulting from the sliding contact between the binder and the sheet metal. The friction force was found to be directly proportional with the coefficient of friction and the binder load. Restraining forces in flat binders are largely

determined by the binder load. Hydraulic or pneumatic cushions with constant binder load during forming have been used to provide the blankholding action in many press systems.

During stamping, the flange tends to thicken in specific areas, and this thickening tendency is highly dependent on the normal anisotropy of the sheet metal. Flange thickening results in the development of separating forces that exceed the binder load and therefore increase the gap between the binder surfaces. This tendency to open up the binder can be a problem in stamping because the increased gap reduces the restraining force needed to form the desired part. To account for the nonuniform thickening in the flange, binders undergo "spotting," which consists of local grinding of a specific area, by trial and error, to produce a more uniform distribution of binder load.

A uniform pressure in the binder area can be achieved without "spotting" by using die cushion pins to flex the binder. The cushion pins extend through the bolster such that the binder load can be concentrated in certain areas. The height of the pins can affect the distribution of the binder load. Other methods for locally controlling binder load distribution involve segmented binders, shown in Fig. 53. Different segments can be independently actuated by hydraulic cylinders to give spatial and temporal binder load control.

### Forming of Ribs, Beads, and Bosses

Unsupported sheet metal surfaces that may buckle or oil can are often stiffened by the addition of long, thin bosses called beads or ribs. Round or nearly round bosses are sometimes called buttons. Dimples are occasionally used as a recess for a rivet or screw head. The forming of ribs, beads, and bosses is a combination of bending, stretching, and drawing and involves high shear forces.

**Design of Bosses.** Bosses are usually approximately one stock thickness in depth. The radius of curvature on the inside of bends is approximately one stock thickness. A typical

**Fig. 52** Use of draw beads. (a) Conventional. (b) Locking. (c) Combined conventional and locking. Dimensions given in inches

bend appears to be approximately four stock thicknesses wide on the convex side and approximately three stock thicknesses wide on the concave side. Some recesses for screw heads have sloping sides with very little curvature.

Bosses are typically produced at the same time that other forming operations are done and in the same dies, although they can be formed at separate stations in a progressive die. Die clearances can be critical in the forming of decorative bosses and embossed lettering, especially when definition must be sharp and detail must be accurate. On the other hand, reinforcing beads usually do not require great accuracy and can be produced in dies with the clearances typical of ordinary forming.

**Use of Bosses.** Bosses are often used to provide flatness, stiffness, and reinforcement to formed parts. They can also serve as locators for subsequent operations. In example 20, an oval boss was used as a hole-locating surface and as the hole flange. The most frequent use of embossed beads is to lighten the weight of products by making it possible to use thinner metal than would be feasible without bosses, as described in the following example.

**Example 22: Use of a Bead for Stiffening a Corner Bracket.** The corner bracket shown in Fig. 54 had a bead on the flat surface to produce stiffness. The work material was 1.09 mm (0.043 in.) thick cold-rolled 1008 or 1010 steel. The bead made the use of heavier stock unnecessary. A short flange around the periphery of the bracket also added to the stiffness.

The bracket was produced in a progressive die in the following operations: trim to shape, pierce, form bead, form flange, and pinch trim from the carrier strip. The die was run in a 4.45 MN (500 tonf) press operating at 600 strokes per hour. Forming of the bead caused some distortion of the pilot holes and resulted in stretcher strains that extended from the inside radius of the bead to the edge.

**Fig. 53** Flexible flat binder with individually controlled hydraulic cylinders

The progressive die was made of D2 tool steel hardened to 62 to 64 HRC. One hour per week was needed to clean the die and to make minor repairs. Die lubricant was chlorinated oil.

## Shells

Shells are produced in various ways, as described in this section adapted from Ref 12. For shells, a special type of press forming is deep drawing, where flat blank is pressed into a die opening to draw the metal into the desired shape without folding of the corners (see the article "Deep Drawing" in this Volume).

**Doubly Contoured Shells.** In forming doubly contoured shells, the major problem is in controlling wrinkling in the outer portion of the blank. In thin materials, which are prone to wrinkling, it is usually necessary to incorporate a blankholder to constrain the outer edge. Alternatively, for lower-volume production, the use of rubber pad, urethane, or fluid forming techniques may be used. When a blankholder is used, the material is stretch formed over the punch, and stretching limits can be determined by measuring the initial blank length,  $R_1$ , and the final perimeter length of several cross sections through the center of the part,  $R_2$ , and using the maximum  $R_2/R_1$  values given in Table 19 for stretch flanging.

**Deep Recessed Shells with Vertical Walls.** In these shells, the walls are produced by drawing in the outer portion of the original blank, then bending the material through 90° and restraughtening it. Due to the reduction in diameter of the blank, compressive circumferential stresses are developed, and wrinkles will tend to form in the outer flange (analogous to the buckling of a thin plate under compression)—the thinner the material, the more prone to wrinkling.

Fig. 54 Corner bracket that was stiffened by beading and flanging. Dimensions given in inches

To prevent this, pressure is applied by means of the blankholding plate—for mild steel sheet, the interfacial pressure is typically 2 to 3.5 MPa (0.3 to 0.5 ksi), and for austenitic stainless steel 10 to 14 MPa (1.5 to 2.0 ksi).\*

In the initial stage of the draw, the blank is stretched across the punch (Fig. 55a). As the punch is pushed through the draw ring, the metal is bent over the die radius and straightened into the cup wall (Fig. 55b). The outer portion of the blank is reduced in diameter as the metal is drawn in (Fig. 55c). The load required to shrink the blank and to bend and unbend the metal over the die radius is carried by the wall. Therefore, the strength of the wall controls the maximum size of shell that can be drawn. An analysis of wall thickness shows that there are two thin areas at which fracture may occur. The most common fracture is at the nose of the punch, where the material was stretched between punch and die in the initial stage of the draw—this is related to the punch radius, as shown in Fig. 56. The punch radius should be above  $6t$  for drawing-grade mild steel and  $4t$  for austenitic stainless steel (where  $t$  is the thickness of the material) to avoid severe thinning.

The second region occurs further up the wall, above the die impact line, that is, in the drawn region where the strain history is complex. The material has been reduced in diameter, bent and unbent under tension while passing over the draw radius, and then carries the high tensile load to draw in the remainder of the blank. This thin area can be related to the draw radius (Fig. 57), which should be greater than  $8t$  for drawing-grade mild steel and  $10t$  for austenitic stainless steels to prevent severe thinning. However, the die radius should not be too great, because the conventional

flat blankholder does not contact the blank over the draw radius, and control of wrinkling may be difficult, especially near the end of the draw.

A third form of fracture may be encountered in deep draws when the die-profile radius is too small. This takes the form of a vertical crack in the wall and is found most often in thick-walled cups when  $t/d > 0.1$  (Fig. 58).

As mentioned previously, it is usual to subdivide this category into shallow circular shells, deep circular shells, wide-flanged circular shells, and rectangular and noncircular shells.

### Shallow Circular Shells with Vertical Walls

**Walls.** These shells are produced in a one-stage draw. The maximum height of flat-bottomed shell that can be achieved in typical commercial practice for drawing-quality rimmed steel is generally assumed to be  $h/d \sim 0.75$ . This assumes that the optimal die-profile radius and punch-profile radius, a moderate punch speed (200 mm/s, or 8 in./s), and a good drawing-compound-type lubricant are used. Deeper shells are produced with improvement in steel grade, and the effect is summarized in Table 20.

The effect of altering punch-profile radius and die-profile radius is shown in Fig. 59 and 60 for drawing-grade rimmed steel and austenitic stainless steel, respectively.

The use of better lubricant and slower press speeds should improve the limits for rimmed or capped steels. In the case of continuously cast aluminum stabilized steel, there is evidence to suggest that higher press speeds (5000 mm/s, or 200 in./s) will improve the drawability. Much more significant improvements are obtained by the use of fluid forming, in which the female die is a rubber diaphragm backed by hydraulic fluid at high pressure. During the draw, the water becomes pressurized and is squeezed out between the die and the shell, providing lubrication over the die radius and, more importantly, forcing the material against the punch, which reduces thinning over the punch nose. The limiting draw ratio,  $D/d$ , may be improved from 2.0 to 2.5 and the height-to-diameter ratio,  $h/d$ , from 0.75 to 1.3 for drawing-quality rimmed steel by this process.

The limits given previously have been for flat-bottomed shells but also apply to contour-bottomed shells where  $h$  is the height of the vertical portion of the wall, provided the material is not too thin,  $t > d/100$ .

To determine the blank diameter,  $D$ , for a given shell diameter,  $d$ , and height,  $h$ , the following formula is used:

$$D = \sqrt{d^2 + 4d \cdot h}$$

This is shown in terms of  $D/d$  versus  $h/d$  in Fig. 61.

The punch force to draw the shell is given by

$$F = \pi d t S (D/d - k)$$

\*These interfacial pressures are for controlling wrinkling only. Higher pressures are used when it is necessary to hold back the blank, as in tapered shells.

Table 19 Limiting radii for contour flanging

Material	Thickness		Maximum $R_2/R_1$	
	mm	in.	Stretch flanging	Shrink flanging
Deep-drawing grade	1	0.04	1.44	1.10
Aluminum-stabilized steel	2	0.08	1.44	1.20
Drawing-grade rimmed steel	1	0.04	1.38	1.10
Cold-rolled mild steel	1	0.04	1.22	1.10
Hot-rolled mild steel	2	0.08	1.18	1.20

$R_1$ , initial blank length;  $R_2$ , final perimeter length

where  $S$  (MPa) is the ultimate tensile strength of the material,  $k$  is usually 0.6 to 0.7, and  $F$  is in Newtons, provided  $d$ ,  $D$ , and  $t$  are in mm.

**Deep Circular Shells.** For deep cups, multistage drawing must be used, as shown in Fig. 62. The reduction of diameter in each stage is lower with succeeding stages. Table 21 gives practical maximum values for reduction in diameter and height-to-diameter ratios achieved in four successive stages using the optimal die- and punch-profile radii, a good drawing compound, and drawing-quality rimmed steel sheet. Figure 61 also shows the number of stages necessary as a function of height-to-diameter ratio.

Substantially deeper draws, better control, and less likelihood of wrinkling can be obtained by

reverse redrawing instead of conventional redrawing. In this process, the shell is turned inside out while reducing its diameter (Fig. 63). The flexure of the metal as it passes over the die radius is then all in one direction rather than first flexing one way then the other, as in conventional redrawing (Fig. 64). Reverse redrawing also has the advantage that it can be accomplished in one stroke of a triple-action press or double-action press with die cushion. Also, greater interstage reductions are possible (Table 22).

**Wide-Flanged Shells.** The additional flange to the shell is, of course, drawn in by the wall and therefore raises the load carried by the wall. Thus, the maximum height that can be drawn in one stage is reduced. Figure 61 gives a plot of the blank size necessary and the number of stages

required to draw a flanged shell as a function of height to diameter and flange width,  $f$ . Again, the optimal die- and punch-profile radii and a good lubricant are assumed.

**Rectangular Shell.** The depth of rectangular shells drawn in one operation is basically dictated by corner radii. Table 23 gives the maximum height-to-width ratio for square or rectangular shells as a function of corner radius to shell width. Die-profile radius and punch-profile radius are assumed to be the optimum ( $10t$  and  $8t$ , respectively) for drawing-quality rimmed sheet steel.

As in the case of all deep-drawn shells, it is important to use the correct blank size and shape in order to decrease the stresses in the walls and reduce the probability of fracture. If a

**Fig. 56** Effect of increasing punch-profile radius on thickness strain (using constant blank diameter).  $t$ , material thickness

**Fig. 57** Effect of increasing die-profile radius on thickness strain (using constant blank diameter).  $t$ , material thickness

**Fig. 58** Three types of failure in deep drawing. (a) Fracture over punch nose; punch nose radius is too sharp. (b) Chevron fracture in wall; die-profile radius is too sharp. (c) Vertical crack in thick-walled cups; die-profile radius may be too sharp, and blank edge may be poor.

**Table 20** Maximum height and draw ratio of the single-drawn shallow flat-bottomed circular shell

Material grade	Maximum $h/d$	Maximum $D/d$
Drawing-quality rimmed steel	0.75	2.0
Deep-drawing-quality aluminum-stabilized steel	0.85	2.1
Low-carbon, niobium-stabilized, cold-rolled steel	1.1	2.25
Hot-rolled drawing-quality steel	0.7	1.9
Austenitic stainless steel grade 302	0.75	2.0

$h$ , height;  $d$ , shell diameter;  $D$ , blank diameter

**Fig. 59** Effect of die-profile radius and punch-profile radius on maximum draw ratio of single-stage cup drawn in drawing-quality mild steel.  $D$ , blank diameter;  $d$ , shell diameter;  $t$ , material thickness

**Fig. 60** Effect of die-profile radius and punch-profile radius on the maximum draw ratio of a single-stage cup drawn in austenitic stainless steel.  $D$ , blank diameter;  $d$ , shell diameter;  $t$ , material thickness

**Fig. 61** Relationship of blank diameter ( $D$ ) to cup height ( $h$ ) and flange width ( $f$ )

rectangular blank is used for pressing a rectangular shell, then large ears will remain at the corners after pressing (Fig. 22).

It is general practice to cut the corners of the blank in order to avoid the ears and even up the flow. Figure 65 shows a worked example for a rectangular pressing 355 mm by 89 mm by 76 mm (14 by 3.5 by 3 in.) deep with a 19 mm (0.75 in.) flange. First, the rectangular blank dimensions are calculated by measuring the total perimeter along the major and minor center lines. Then, the amount of corner cutting is determined by reference to Fig. 66. In cases that may be critical, the blank is developed further by

rounding the cut corners, as shown in Fig. 67 (there are three examples, depending on whether  $R = 0.65$ ,  $R > 0.65$  or  $R < 0.65$ ).

**Table 21** Maximum reductions in diameter and cup height/diameter ( $h/d$ ) for successive redraws of drawing-quality rimmed steel

Draw stage	$\frac{d_i}{d_{i-1}}$	$\frac{D_{\text{blank}}}{d_i}$	$\frac{h_i}{d_i}$
First draw	0.53	1.90	0.75
Second draw	0.75	2.50	1.30
Third draw	0.84	3.00	~2.0
Fourth draw	0.86	3.50	~2.8

**Fig. 62** Redrawing operation. The optimal die throat angle for redrawing thin sheet steel is  $30^\circ$ . When a drawn shell A is to be redrawn, it is placed over the draw collar B (with dies open). Partially redrawn shell illustrates how metal is caused to flow into a shell of smaller diameter and greater length. Metal flow is caused by descent of die ring D against the resistance of the draw collar B, supported by the pressure pins C. The draw collar will strip the shell from the punch during the press upstroke.

**Fig. 63** The reverse redrawing operation. Three steps in reverse drawing a small thick walled shell. (a) The shell is placed over the die member. (b) The punch turns the shell inside out. (c) The reduced shell will be stripped by the sharp edge in the die cavity when the punch ascends.

Another approach that has been used is to leave the corners of the blank uncut, so that fracture high in the corners is eliminated, and deeper shells can be obtained. The difficulty is in controlling the flow of material in the sidewalls, leading to slackness and oil canning effects.

Blank orientation can play a major part, because commercial capped and stabilized drawing-quality steels develop the highest  $r$ -values (i.e., best resistance to thinning) parallel and at right angles to the rolling direction. If the blank can be oriented with these directions running

into the corners, then deeper shells will be obtained. However, unless the developed blank has substantial corner cutting, this will lead to extra scrap in cutting blanks from coil (Fig. 68). Improvements in shell depth of 30 to 40% can be achieved using the low-carbon steels with high  $r$ -values at  $45^\circ$  to the rolling direction, especially for shells with tight corners,  $r/w < 0.2$ .

Another variable used to control blank flow is the flexing of the blankholder plate by inserting shims between the plate and blankholder bolster to provide higher local pressures on the blank.

This can be very effective and completely alter the flow pattern. For a rectangular shell, the shims are usually placed to hold the sides back and encourage the corner to flow in. Draw beads can be used in a similar manner and provide more effective control; however, they tend to leave galling marks on the part.

Very deep rectangular pans should be drawn in two operations, following the procedure shown in Fig. 69. The width and length of the first-stage shell should be larger than the final shell by approximately three times the final corner radius.

**Fig. 64** Flexure in redrawing. (a) Reducing a shell supported by a collar causes the metal to flow inward  $90^\circ$  then upward  $90^\circ$ . (b) Reverse drawing also causes  $180^\circ$  flexure, but in one direction. (c) Overstressing can occur if the metal is pulled through more than  $180^\circ$ .

**Fig. 65** Laying out the blank. The dimensions of the rectangular blank are established as  $X = 264$  mm (10 in.) and  $Y = 531$  mm (21 in.) by measuring the perimeter along the major and minor center lines. Mark out the positions of the center lines and then the positions of the centers of the corner radii. This establishes  $B = 64$  mm (2.5 in.) and  $C = 330$  mm (13 in.). From the four center points, scribe a radius selected from figures for the corner radii of 13 mm (0.5 in.) and depth of 76 mm (3 in.). This gives  $R = 47$  mm (1.9 in.), with the note that this will be a difficult pressing and will probably require further blank development. Add  $\leq 17$  mm (0.7 in.) to  $R$  to allow for the flange to give  $R = 64$  mm (2.5 in.).

**Table 22** Maximum reductions in diameter for successive reverse redraws

Draw stage	$\frac{d_i}{d_{i-1}}$	$\frac{D_{\text{blank}}}{d_i}$	$\frac{h_i}{d_i}$
First (conventional) draw	0.53	1.90	0.75
Second (reverse) redraw	0.70	2.70	1.50
Third (reverse) redraw	0.75	3.60	$\sim 2.9$

**Table 23** Maximum height-to-width ratios ( $h/w$ ) for square or rectangular shells drawn in one operation as a function of corner radius-to-width ratio ( $r/w$ )

$r/w$	$h/w$
0.4	1.0
0.3	0.9
0.2	0.76
0.15	0.65
0.10	0.50
0.05	0.30
0.02	0.12

Note: These figures are conservative, especially for  $r/w < 0.15$ ; however, considerable blank and die development will be necessary if they are exceeded.

**Fig. 66** Plot for determining amount of corner cutting,  $R$ , as a function of corner radius,  $r$ , and height,  $h$

The corner radius in the first stage should be four to five times the final corner radius, and the punch-profile radius should be approximately 1.5 times the final corner radius.

**Deep Recessed Shells with Sloping Walls.** Shells with sloping walls are more difficult to produce than shells with vertical sides because of the unsupported material in the sidewalls, which will tend to buckle or pucker. As explained previously, the blank will attempt to buckle as it is reduced in diameter. The blankholder prevents this, but after the material has passed the die orifice and moves into the

shell wall, it is not constrained by a blankholder, and with further reduction in diameter, it will tend to pucker. Puckering can only be prevented by stretching the material. Failure modes are therefore two. The first failure occurs in the stretch region over or near the punch nose and is related to the work-hardening ability of the material, punch-profile radius, and coefficient of friction between punch and blank. The second failure is puckering in the sloping wall and is related to the angle of taper and the material-thickness-to-shell-diameter ratio. Obviously, the thicker the material, the greater will be its

resistance to puckering. For thickness,  $t > d/100$ , where  $d$  is the die orifice diameter, puckering does not occur.

Because puckering is prevented by stretching the material in the shell wall, the drawing process is controlled by the blankholder force. At low blankholder force, the walls will pucker at low shell depths; as the blankholder force is increased, deeper shells will be drawn before puckering occurs. At high blankholder force, the metal will fracture over the nose of the punch, and as blankholder force is increased further, the shell height will reduce. A plot of shell height against blankholder force (Fig. 70) illustrates this effect.

There is an optimal blankholder force that produced the deepest shell. At this force, both wall puckering and splitting over the punch nose occur simultaneously at the failure point. The difficulty of drawing a shell of a given height can be determined from this plot; for example, a shell drawn to half maximum height can be produced over a wider range of blankholder force than a shell drawn to three-quarter maximum height, and therefore it will be a less critical draw.

The curves in Fig. 71 illustrate the importance of metal thickness in drawing tapered shells; doubling the metal thickness allows the shell to be drawn 50% deeper through a die throat diameter of 100 mm (4 in.) with a punch diameter of 75 mm (3 in.). The effect of sheet steel grade is seen in Fig. 72; changing from rimmed drawing-quality to aluminum-stabilized deep-drawing-quality steel improved the depth of shell by 20% through a 203 mm (8 in.) die throat diameter.

General rules for tapered shells are:

- Shallow tapered shells with height less than one-quarter the diameter at the open end,  $d$ , and with thickness  $t > d/200$  can be drawn in one operation.

Fig. 67 Development of blank corners for rectangular shells

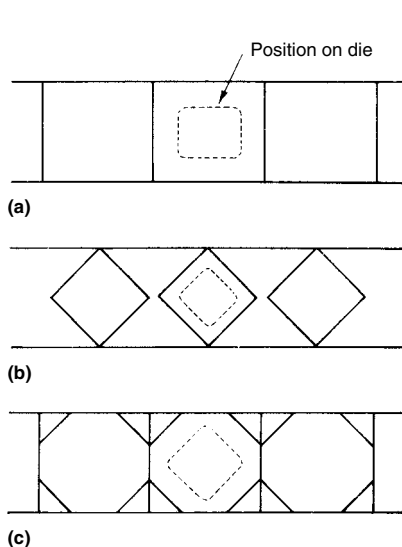

Fig. 68 Methods of cutting blank from coil for drawing-quality rimmed and aluminum-stabilized steels. (a) Blanks cut across rolling direction. (b) Blanks cut at 45° to rolling direction; produces high scrap but deeper draws. (c) Blanks cut at 45° to rolling direction for deepest draws. Scrap is reduced when corner cutting is used.

Fig. 69 Profiles of first and second stages in drawing a very deep rectangular shell with tight corner radius,  $R$

Fig. 70 Drawing of a tapered shell—a typical plot of depth of shell against blankholder force. The shallower the shell, the greater the latitude in blankholder force to produce a successful shell.

**Fig. 71** Depth of a tapered shell as a function of blankholder depth. The effect of metal thickness and blank size is shown. Die orifice diameter is 100 mm (4 in.), and punch orifice diameter is 75 mm (3 in.).

- Tapered shells with  $\frac{1}{4} < h/d < \frac{1}{2}$  should be drawn into a similar shape having vertical or a small taper in a preliminary operation.
- Deep tapered shells with  $h/d > \frac{1}{2}$  must be drawn first into stepped shells having vertical walls and then stretched to shape in a final operation.
- where  $t < d/100$ , tapered shells can be drawn to between  $0.4d$  and  $0.5d$ , provided the punch-profile radius is  $10t$  or greater. However, the sides will tend to bow out at the top, and control of the shape will be difficult unless matching male and female dies are used and the part is coined in the dies at the bottom of the stroke.

**Hemispherical Shells.** As with tapered shells, the main problem encountered in drawing spherical shells is puckering. To avoid this, blankholder forces are higher than in drawing vertical-sided shells, in order to control flow and promote stretching.

The important parameters in the drawing of spherical shells are height of crown,  $h$ ; diameter of blank,  $d$ ; thickness of material,  $t$ ; and flange width,  $f$ .

A full hemisphere can be drawn to a diameter equal to  $100t$ , and this diameter can be pro-

**Fig. 72** Drawing of tapered shell, showing the effect of steel grade on depth of shell. Die orifice diameter is 203 mm (8 in.), and punch diameter is 150 mm (6 in.).

portionately increased as the height of the shell is decreased.

Shallow shells give problems with springback, and to counteract this, the flanges must be drawn to a larger diameter, and the shell to a greater depth.

When controlling flow, it is sometimes found that the blankholder force is insufficient, and recourse is then made to:

- Oversized blanks, giving an increase in the area acted on by the blankholder
- Draw beads, which provide localized resistance to flow in the required areas

When a shell proves impossible to produce in a single operation, either:

- A two-piece punch is used. This is a method of reducing the pull exerted by a domed punch by dividing the punch into two parts that act separately.
- The shell is drawn in two operations, where the final shape is either stretched or redrawn from a straight-walled shell.

**Special Shells.** A special shell is one in which the body is not concentric with other parts of the shell, or the flange at the open end is not parallel with the bottom, or the shell is made up of a

combination of straight, tapered, and spherical surfaces. Most special shells have sections shaped like the common shells covered previously, and it is possible to make judicious use of the rules for the parts in combination to produce the die design for the special shell.

# Forming of Advanced High-Strength Steels

Mahmoud Y. Demeri, FormSys Inc.

THE STEEL INDUSTRY has responded to competition from alternative materials for lightweighting and performance enhancements by developing new steel grades with superior product attributes to leverage steel as the optimal automotive material. New technologies such as continuous casting and thermomechanical processing have resulted in the development of several new grades of steel. High-strength low-alloy (HSLA) steels achieve their good combination of formability and weldability through microalloying. Advanced high-strength steels (AHSS) such as dual-phase (DP), complex-phase (CP), and transformation-induced plasticity (TRIP) steels show superior strength compared to the HSLA grades with the same formability. The AHSS derive their superior mechanical and forming properties from their final microconstituents (ferrite, bainite, martensite, and retained austenite). For example, DP steels derive their strength from the martensite phase and their ductility from the ferrite phase. Automotive engineers are specifying increased amounts of AHSS to achieve greater strength without a corresponding increase in weight.

Interest in the automotive applications of high-strength steels (HSS) and AHSS is based on the many advantages that such materials offer over mild steel, aluminum, and magnesium alloys. Some of these advantages are:

- Weight reductions through reduced sheet thickness
- Safety improvement through high crash resistance
- Better appearance through elevated dent resistance
- Better performance through increased fatigue strength
- Cost reduction through reduced material use due to down-gaging
- Cost savings through material cost compared to aluminum and magnesium
- Fuel economy improvement through weight reduction

## Classification of HSS and AHSS

The HSS and AHSS have been developed to improve the strength-to-weight ratio of low-carbon steels. Higher strengths are achieved by

microalloying, melting practice, heat treatment, or a combination of these. The HSS and AHSS cover a wide range of properties and strength levels. A number of arbitrary definitions of the classes of such materials have been developed. The American Iron and Steel Institute (AISI) designation of HSS and AHSS is shown in Table 1.

The International Ultralight Steel Auto Body (ULSAB) Consortium (Ref 1) defines the strength levels of mild steel, HSS, and AHSS as shown in Table 2.

It is important to realize that some HSS may be designated by minimum tensile strength and not by minimum yield strength. To provide a consistent nomenclature, the ULSAB Consortium adopted a standard practice that defines both yield strength and ultimate tensile strength. In this classification system, HSS and AHSS steels are identified as:

XX aaa/bbb

where XX is the type of steel, aaa is the minimum yield strength in MPa, and bbb is the minimum ultimate tensile strength in MPa.

The steel type designator uses the classification shown in Table 3 (Ref 1).

As an example, a classification of DP 500/800 refers to dual-phase steel with 500 MPa (73 ksi)

minimum yield strength and 800 MPa (116 ksi) minimum ultimate tensile strength.

The strength levels of HSS are achieved by using steel grades such as rephosphorized, high-strength interstitial-free (HS-IF), bake-hardenable (BH), microalloyed (HSLA), and phosphor-alloyed steels. The strength levels of AHSS are achieved by using steel grades such as dual-phase (DP), transformation-induced plasticity (TRIP), complex-phase (CP), and martensitic (MART) steels. Such steels are available in hot-rolled, cold-rolled, and zinc-coated products. Coatings may be electrogalvanized or hot dipped.

The principal differences between HSS and AHSS are due to their microstructures. The HSS have small amounts of alloying elements to attain high strength levels. The AHSS are multiphase steels that contain martensite, bainite, and/or retained austenite in quantities sufficient to produce distinct mechanical properties. They exhibit a superior combination of high strength with good formability and high strain hardening capacity. Typical values of mechanical and forming properties of some HSS and AHSS steel grades are given in Table 4 (Ref 1).

Figure 1 shows the relationship between total elongation and ultimate tensile strength for some of the HSS and AHSS grades. The figure is adapted from a study commissioned by AISI and the United States Department of Energy (DOE) to advance the use of HSS and AHSS in the North American automotive industry (Ref 2).

Figure 1 shows that ductility, as measured by percent total elongation, decreases with increasing the ultimate tensile strength of steels.

**Table 1 American Iron and Steel Institute designation of high-strength steel and advanced high-strength steel**

Steel type	Yield strength	
	MPa	ksi
High-strength steel	255–550	37–80
Advanced high-strength steel	> 550	> 80

**Table 2 Ultralight Steel Auto Body definition of mild, high-strength steel, and advanced high-strength steel**

Steel type	Yield strength	
	MPa	ksi
Mild steel	140–<210	20–<30
High-strength steel	210–550	30–80
Advanced high-strength steel	> 550	> 80

**Table 3 Type classifications for high-strength steels and advanced high-strength steels**

Designation	Type
<b>High-strength steels</b>	
BH	Bake hardenable
HSLA	High strength low alloy
<b>Advanced high-strength steels</b>	
DP	Dual phase
TRIP	Transformation-induced plasticity
MART	Martensitic
CP	Complex phase

The objective of the AISI/DOE formability project was to conduct tests on HSS and AHSS grades to characterize mechanical behavior and material limits under different forming conditions. Table 5 summarizes the results of the AISI/DOE project (Ref 2).

**Strengthening in HSS and AHSS** includes one or more of the following mechanisms (Ref 3):

- Solid-solution hardening (alloying)
- Precipitation hardening
- Grain-refinement hardening
- Phase-transformation hardening (heat treating and deformation-induced austenite-to-martensite transformation)

Many HSS and AHSS grades, such as BH, HSLA, and DP steels, are commercially available and are used in the current production of automotive components. Other grades, such as TRIP and CP, are under development and available only in laboratory quantities.

Substituting HSS for mild steel in an automotive body structure may reduce its weight by approximately 40% without compromising its performance (Ref 4). In general, a weight reduction of 10% can increase the fuel economy of a vehicle by approximately 8%.

## Review of HSS and AHSS Grades (Ref 3)

The following is a review of the major grades of HSS and AHSS that are currently used or will potentially be used in industrial applications.

**Bake-Hardening Grades.** The BH steels have a good combination of strength and formability. This combination makes them ideal for dent-resistance auto applications such as hoods, doors, and fenders. The increase in yield strength in this class of steel results from strain hardening and strain aging during paint baking after the stamping process. Bake hardening produces an increase in yield strength ranging from 28 to 56 MPa (4 to 8 ksi) after a low-temperature heat treatment cycle similar to a paint-bake schedule (175 °C, or 345 °F, for 20 to 30 min). The bake-hardening effect is possible only if the steel has undergone low plastic deformation of <5% and has been exposed to a baking temperature of at least 150 °C (300 °F). These steels are appropriate for some low-deformation body panels.

**High-Strength Low-Alloy Grades.** The HSLA steels have small amounts of alloying elements, such as phosphorus, manganese, or silicon, added to low-carbon (0.02 to 0.13% C) steels to attain high strength levels. In these

steels, higher strength is achieved by rapid cooling to produce a very fine ferrite grain size; by solid-solution strengthening with phosphorus, nitrogen, silicon, and manganese; and by formation of carbides or carbonitrides with vanadium, nickel, and titanium. These steels have better mechanical properties, corrosion resistance, and weldability than mild steels. The HSLA steels are produced as hot-rolled products and cold-rolled sheet. These steels can achieve yield strengths up to 485 MPa (70 ksi) without heat treatment. This class of steel has low formability and is used for shallow drawn parts.

**Dual-Phase Grades.** The duplex microstructure of DP steels is comprised of a soft ferrite matrix and between 20 and 70% volume fraction of martensite. The volume fraction of martensite determines the strength level of this steel. Special heat treating practices that involve quenching and tempering are used to generate the martensite phase. The DP structure is produced by quenching low-carbon steels from the alpha + gamma phase region to form a microstructure of martensite islands in a ferrite matrix. This microstructure gives DP steels their high strain hardening capability and better formability compared to HSLA grades. For a given yield strength, the tensile strength of DP steels is also higher than HSLA steel (Fig. 2).

**Table 4 Mechanical properties of some high-strength steel and advanced high-strength steel grades**

Steel grade(a)	Minimum yield strength		Minimum ultimate tensile strength		Total elongation(b), %	n-value (5–15%)(b)	Average strain ratio ( $r_m$ or $\bar{r}$ )(b)	K-value(b)	
	MPa	ksi	MPa	ksi				MPa	ksi
BH 210/340	210	30	340	49	34–39	0.18	1.8	582	84
BH 260/370	260	38	370	54	29–34	0.13	1.6	550	80

**Table 5 Summary of American Iron and Steel Institute/Department of Energy formability project**

Formability attribute	Test method	Formability parameters characterized	Factors influencing formability
Forming limits	Full dome test	Forming-limit diagram	n-value, thickness
Sheared-edge stretching limits	Hole extrusion test	% hole expansion	Ultimate tensile strength (UTS), $r$ -bar value
Bending under tension limits	Angular stretch-bend test	Height at failure, stretch-bendability index	UTS, $r$ -bar value
Springback and curl	Channel draw test	Springback opening angle, radius of sidewall curl	Yield strength, tool radii, draw bead restraining force, tool gap
Stretch formability	Pan forming (fully locked conditions)	Height at failure	n-value, thickness
Stretch drawability	Square draw test	1. Height at failure 2. Binder control 3. Strain measurement	Uniform elongation, $r$ -bar, blank size, coating, lubrication

The DP steels are designed to provide ultimate tensile strengths of 600 to 1000 MPa (87 to 145 ksi). The DP steels can also exhibit a bake-hardening effect, which is the increase in yield strength resulting from prestraining and elevated-temperature aging. The extent of the bake-hardening effect in AHSS depends on the specific chemistry and thermal histories of the steels. Dual-phase steels are usually bake hardened.

**TRIP Grades.** The TRIP steels consist of two phases: a ferrite/bainite matrix and a 5 to 20% volume fraction of metastable retained austenite, which progressively transforms to martensite during plastic deformation. This combination of phases gives TRIP steels the high formability of austenite during the initial stages of the stamping process, followed by the high strength of martensite at the end of the forming process.

The TRIP steels are characterized by strain hardening rates higher than DP steels (Fig. 3), high tensile strengths, and ductility. The high strain hardening rate of TRIP steels is one reason for improved formability. The progressive transformation of retained austenite to martensite in TRIP steels also leads to microstructural volume and shape changes that accommodate strain and increase ductility. The transformation thus provides strengthening and extends strain beyond that of DP steels (Fig. 2).

The excellent formability of TRIP steels combined with their high strength make them attractive candidate materials for lightweight applications. Also, because the martensite formation occurs at extremely fast rates, the TRIP phenomenon occurs even at high deformation rates, as encountered during vehicle crash conditions. Therefore, TRIP steels are also being considered for applications requiring maximization of crash energy absorption.

**Complex-Phase Grades.** The CP steels consist of a very fine microstructure of ferrite and a higher volume fraction of hard phases that are further strengthened by fine precipitates. They use many of the same alloy elements found in DP and TRIP steels but additionally have small quantities of niobium, titanium, and/or vanadium to form fine strengthening precipitates. Complex-phase steels provide ultimate tensile strengths of 800 MPa (116 ksi) and greater. They are characterized by high deformability and high energy absorption, which makes

**Fig. 2** Stress-strain curves for high-strength low-alloy (HSLA), dual-phase (DP), and transformation-induced plasticity (TRIP) steels with 350 MPa (50 ksi) yield strength. Source: Ref 5

them ideal candidates for automotive crash applications, such as bumper and B-pillar reinforcements.

**Martensitic Grades.** The MART steels contain a high fraction of martensite. The microstructure is low-carbon martensite, with the carbon content determining the strength level of the material. The austenite that exists during hot rolling or annealing of the material is transformed to martensite during quenching and/or postforming heat treatment. Martensitic steels are often subjected to postquench tempering to improve ductility and can provide good formability even at extremely high ultimate tensile strengths of up to 1500 MPa (217 ksi). Carbon is added to martensitic steels to increase hardenability and also to strengthen the martensite. Elements such as manganese, silicon, chromium, molybdenum, boron, vanadium, and nickel are also used in various combinations to increase hardenability.

**High-Hole-Expansion (HHE) Steels.** The AHSS microstructures result in improved total elongations, but these same microstructures also reduce local elongations or ductility (measured by hole-expansion factor,  $\lambda$ ) that affect hole expansion, stretch flanging, and bending. In responses, HHE steel is an area of development for applications that require a high degree of sheared-edge elongation (hole flanging). The key to improved sheared-edge stretchability is a homogeneous microstructure, such as a single phase of bainite or multiple phases with bainite

**Fig. 3** Instantaneous  $n$ -values versus strain for transformation-induced plasticity (TRIP), dual phase (DP), and high-strength low-alloy (HSLA) steels. Source: Ref 5

(Fig. 4), and the removal of large martensitic constituents. The multiple-phase microstructure is primarily ferrite and bainite with some retained austenite. Parts stamped from these grades are replacing cast and forged parts (Ref 7).

## Properties of HSS and AHSS (Ref 3)

**Plastic Flow.** A comparison between typical engineering stress-strain curves of various grades of cold-rolled, hot dip galvanized HSS and AHSS (HSLA 340, DP 600, TRIP 700) is shown in Fig. 5.

The figure shows a significant increase in the tensile strengths of these materials compared to mild steel. The materials also shows superior crash performance due to the energy-absorption capability that results from their high toughness. The true stress-strain curves of various HSS and AHSS grades (HSLA 300, DP 600, TRIP 800, CP 1000) are shown in Fig. 6. Mild steel is included for reference.

**Strain Hardening.** A high strain hardening capacity positively influences formability by resisting local necking during stamping and is especially important in the stretch-forming

**Fig. 4** Improvements in hole expansion by modification of microstructure. TRIP, transformation-induced plasticity; DP, dual phase. Source: Ref 6

**Fig. 5** Engineering stress-strain curves of various grades of high-strength steel and advanced high-strength steel

deformation modes typically encountered in the manufacture of many automotive body components. High strain hardening capacities also result in higher ultimate tensile strengths in the manufactured component, which enhances crash energy absorption and fatigue performance.

**Strength.** A comparison between typical strength levels of various grades of cold-rolled, hot dip galvanized HSS and AHSS (BH 180, HSLA 220, IF 260, DP 600, TRIP 700, CP 1000) is shown in Fig. 7.

**Ductility and Bendability.** A comparison between the ductility of the same grades of HSS and AHSS is shown in Fig. 8. The HSS and AHSS are more difficult to bend than plain carbon steels because of their higher yield strength and lower ductility. This requires more power, greater bend radius, more die clearance, and greater allowance for springback. It may be necessary to remove shear burrs and to smooth corners in the area of the bend. Whenever possible, the axis of the bend should be perpendicular to the rolling direction. If the bend axis must be parallel with the rolling direction, it may be necessary to use cross-rolled material, depending on the severity of the bend. All HSLA steels are not equal in formability. However, for the more readily formable grades and the quenched-and-tempered grades, the minimum bend radii in Table 6 are recommended.

These minimum bend radii are for bending with the bend axis across the rolling direction. The use of smaller bend radii increases the probability of cracking. Hot bending is recommended for thicknesses greater than 13 mm (1/2 in.).

Hot bending is necessary when the product shapes are too complex or when bend radii are too small for cold forming. The HSLA steels can be successfully hot bent at temperatures as low as 650 °C (1200 °F); however, when maximum bendability is needed, temperatures of 845 to 900 °C (1550 to 1650 °F) are recommended. Cooling in still air from these temperatures returns the material nearly to the as-rolled mechanical properties. Tables in the article "Forming of Carbon Steels" in this Volume show the effect of composition on minimum bend radius by comparing the minimum radii for common grades of carbon and low-alloy steels.

**Springback** is the change in dimension in the shape of the part from that of the shape of the die after forming and unloading the part. It may involve angular change (typically referred to as springback) or sidewall curl of a section. In general, springback depends on the ratio of yield strength to elastic modulus. A higher yield strength or a lower modulus increases springback for a given section thickness and tooling arrangement.

Due to the high ratio of yield strength to elastic modulus of HSS and AHSS, a larger amount of springback, compared to mild steel, develops in the formed part. Springback is of great concern to sheet metal forming tool designers, because it can cause serious problems in the assembly of parts and can lead to expensive modifications of

the forming tools. Springback and sidewall curl after unloading from stamping dies is a very important technical barrier to the widespread use of HSS. Springback can be reduced through

proper tooling design and by controlling the binder forces acting on the drawn sheet.

Recent studies (Ref 8) of springback in U-channel forming of HSLA 350, DP 600, and

Fig. 6 True stress-strain curves of various high-strength steels, advanced high-strength steels, and mild steel

Fig. 7 Strength levels of various grades of high-strength steel (HSS) and advanced high-strength steel (AHSS). YS, yield strength; TS, tensile strength

Fig. 8 Percent elongation of various grades of high-strength steel (HSS) and advanced high-strength steel (AHSS)

TRIP 700 steels showed that springback depends on the strength level of the stamped part (that is, the yield strength after forming). Materials with a high  $n$ -value (DP 600, TRIP 700) show increased strength after forming, which results in higher springback. The study also showed that a reduction of sheet thickness, and therefore an increase in the die gap, increases springback. The amount of springback increases with increase in the strength level of the sheet materials. It was found that the most influential factors controlling springback and curl were the tooling radius and draw bead penetration (see the section "Stamping Issues and Forming Guidelines for HSS and AHSS" in this article).

**Formability.** Forming limits of sheet steel are described by a forming-limit diagram that shows the limit strains of the steel when it is formed through a linear strain path. The formability of various grades of HSS, AHSS, and mild steel (for reference), as determined by the forming-limit diagram, is shown in Fig. 9. The figure shows that formability follows the general trend of decreasing with increase in the strength of the steel.

**Hot Forming of HSLA.** In hot forming, the work metal is heated above its recrystallization temperature. A lower press capacity is needed to hot form a given shape than to cold form it. However, the press, dies, and related equipment

must be designed to withstand high temperature. Meeting this requirement is sometimes more difficult than obtaining a higher-capacity press for cold forming.

In some applications, a steel workpiece can be quenched directly from the forming temperature. In one example, a 25 mm (1 in.) thick HSLA steel blank was hot formed into a bucket blade for earthmoving equipment. The blank was cut by oxyfuel torch to 305 by 1700 mm (12 by 67 in.) from a flat plate, then furnace heated to 815 °C (1500 °F). The hot workpiece was formed with one stroke of a 1.8 MN (200 tonf) hydraulic press. No lubricant was used, because production quantities were small and the surface condition of the part was not critical. After being formed, the part was quickly removed from the die and allowed to cool on the floor. Time from furnace to press to floor was 4 min per piece. Heating the blank to 815 °C (1500 °F) permitted forming in a much smaller press and with greater accuracy than could have been done if the blank had been formed at room temperature. Tolerances of  $\pm 1.6$  mm ( $\pm 1/16$  in.) were maintained on the overall dimensions of the formed part. The forming die was a weldment made of hot-rolled 1045 steel, flame hardened at the critical wear points. Production was 400 buckets per year in lots of 60. Die life was 2400 pieces before reworking.

**Table 6 Minimum bend radii for high-strength low-alloy steels**

Steel thickness( $t$ )		Minimum bend radii for minimum yield strength of:	
mm	in.	310 MPa (45 ksi)	345 MPa (50 ksi)
<1.6	$1/16$	$1/2t$	$1t$
1.6–6.4	$1/16$ – $1/4$	$1t$	$2t$
6.4–13	$1/4$ – $1/2$	$2t$	$3t$

### HSS and AHSS Automotive Applications (Ref 3)

Applications of HSS in the automotive industry revolve around two major areas:

- Improving crash performance (front, rear, side) via increased strength levels
- Reducing weight via gage reduction

**Fig. 9** Forming-limit diagrams for various grades of high-strength steel, advanced high-strength steel, and mild steel

Other important applications criteria include stiffness, fatigue life, corrosion resistance, formability, and weldability. Typical applications of HSS include panels, chassis, and structural components (door beams, wheels, bumpers, seats, suspensions, etc.).

The ULSAB project used 91% of the vehicle weight from HSS and AHSS grades, as shown in Table 7 (Ref 1). The Ultralight Steel Auto Closures (ULSAC) project selected BH 210, BH 260, and DP 600 to develop new concepts for automotive steel closures that can achieve 10% mass reduction while maintaining structural performance with no cost penalty (Ref 9).

Recently, the Auto Steel Partnership (ASP) commissioned a world-wide survey of the automotive applications of HSS (Ref 10). The report concluded that weight reduction and improved crash resistance are the driving forces for using more HSS and AHSS in vehicles. The report also concluded that Europe and Japan are more aggressive in increasing the HSS and AHSS content in their cars. There is a general agreement that the HSS and AHSS content will increase in the Body-in-White (BIW) from its current 10 to 40% to >50% as the availability of DP, TRIP, and CP steels increases.

**Benefits Analysis.** The benefits of using HSS in car body structures and components can be analyzed by using the performance indices that were developed for materials selection. Table 8 shows the performance indices that must be considered for selecting the best materials for car body applications. Performance indices are groupings of material properties developed by Ashby to maximize some aspect of the performance of a component (see the article "Performance Indices" in *Materials Selection and Design*, Volume 20 of *ASM Handbook*, 1997).

**Table 7 High-strength steel (HSS) and advanced high-strength steel (AHSS) grades used in the Ultralight Steel Auto Body project**

Steel type	Yield strength		Amount used, %
	MPa	ksi	
Mild steel	<210	<30	8
HSS	210	30	27
HSS	280	41	13
HSS	350	51	45
HSS	420	61	3
AHSS	>550	>80	3

**Table 8 Performance indices for car body applications**

Application requirements	Performance index(a)
Stiff and light panel	$E/\rho$
Dent and crash resistance of light panel	$(\sigma_y)^{1/2}/\rho$
Tensile/compressive strength of light panel	$\sigma_y/\rho$
Bending stiffness of a light panel	$(E)^{1/3}/\rho$
Buckling stiffness of a light panel	$(E)^{1/2}/\rho$

(a)  $E$ , elastic modulus;  $\sigma_y$ , yield strength;  $\rho$ , density of material

Some of the performance indices are stiffness-specified (specific stiffness) and others are strength-specified (specific strength). Materials with large values of performance indices are the best materials for the intended application.

For example, the table shows that if the critical buckling stress in impact is considered, increasing the yield strength by a factor of 2 raises the critical buckling stress by 50%. This can be achieved with high-strength grades.

**Outer Panels.** High-strength steels are used in outer-body panels for weight reduction, increasing panel stiffness, and improving dent resistance. Most outer panels are made of steel sheets with tensile strength of 260 to 340 MPa (38 to 49 ksi). This may include BH and HSLA grades. The BH steels are often used to make doors, hoods, fenders, deck lids, and truck beds. In such applications, dent resistance is important. Dent resistance (DR) increases with increase in yield strength (YS) and sheet thickness ( $t$ ) in accordance with:

$$DR = K(YS)(t^m) \quad (\text{Eq 1})$$

where  $m = 1$  to 3, and  $K$  is a constant depending on the shape of the panel.

In HSS, the increase in strength can compensate for the decrease in dent resistance due to thickness reduction. This is not the case for panel stiffness (PS), which increases with increase in elastic modulus ( $E$ ) and sheet thickness ( $t$ ) in accordance with:

$$PS = K(E)(t^m) \quad (\text{Eq 2})$$

Reducing sheet thickness for weight savings lowers panel stiffness, and this leads to surface deflection. Because of the negative effect of thickness reduction on panel stiffness, limits on the amount of down-gaging are established. Because outer panels are subjected to bending and buckling, stiffness is more important than strength for this application. In such cases, substitution of HSS and AHSS for mild steel cannot be rationalized.

The ULSAC program demonstrated that mass reduction of approximately 10% could be achieved by using BH 210, BH 260, and DP 600 grades (Ref 9). The mass reduction was achieved while maintaining structural performances and without cost penalty.

**Inner panels** have complicated shapes and are formed by deep drawing. High-strength steels used for this application have tensile strength of 260 to 390 MPa (38 to 57 ksi). This may include BH and HSLA grades. However, because of the limited formability of HSS, complicated inner panels cannot be formed successfully using traditional forming methods.

**Structural and Chassis Components.** Structural parts in automobiles require high crash resistance, which, for a specific part, depends on material fracture toughness and sheet thickness. Most structural components in current production are made of steel sheets with tensile strength of 270 to 540 MPa (39 to 78 ksi). This may include thicker gages of BH, HSLA, and DP 500 grades. Higher-strength steels offer an opportunity for reducing weight by reducing component thickness. A major problem in using higher-strength steels for automotive applications is the increase in springback of the formed parts. For a constant elastic modulus, springback increases with increase in the flow strength of the sheet metal. For structural applications, the yield strength is the major consideration in materials selection. In such cases, HSS and AHSS can be used, and weight savings of 40 to 60% are possible when substituting these materials for mild steel.

The BIW is the heaviest and largest structure in vehicles. It comprises approximately 20 to 30% of the total weight of a medium-sized passenger car. Reducing the mass of BIW by using high-strength can produce significant weight savings and improved crash resistance. Examples of such applications are impact beams, B-pillar reinforcements, and bumper bars. It is anticipated that the HSS and AHSS content in the BIW may increase to over 50% as more of these

materials become commercially available and as new designs and manufacturing methods are implemented.

Applications of DP steels include seat parts, bumpers, door beams, frame components, rails, and pillars. Typical automotive parts for improving crashworthiness include front rails, center pillars, and rear-side members. Side impact resistance has been improved and weight reduction has been achieved by incorporating many DP steel parts in body structures. A 13% weight reduction has been accomplished by using TRIP steel in several suspension parts.

Table 9 shows some typical properties and application examples of various grades of HSS and AHSS (Ref 3).

## Stamping Issues and Forming Guidelines for HSS and AHSS

The ASP has issued a guide for using HSS for BIW applications (Ref 11). The guide explains the steel characteristics and provides guidelines for die design, die construction, and die tryout. It also discusses product design and advanced die-process concepts for forming HSS. Because the properties of HSS are characterized by low elongation and high resistance to compression, splitting and buckling tendencies increase with increase in tensile strength. Parts are designed with minimum draw depth and reduced stretch and compression of the sheet metal to avoid splits. Also, gentle shape transitions are used to avoid wrinkles, and large radii are specified to facilitate metal flow.

**Press Loads.** The energy required to plastically deform steel is proportional to the area under the stress-strain curve. Some of the HSS and AHSS exhibit high strain hardening behavior, which can also be used to estimate the press capacity needed for stamping a part. Higher-than-normal binder pressure and press tonnage is necessary with HSS and AHSS to maintain process control and to minimize

**Table 9 Typical properties and applications of high-strength steels and advanced high-strength steels**

Steel type(a)	Gage		Yield strength		Tensile strength		Elongation, %	Application examples
	mm	in.	MPa	ksi	MPa	ksi

(a) HSLA, high strength low alloy; IF, interstitial-free; DP, dual phase; CR, cold rolled; HR, hot rolled; GA, galvanized and annealed

buckles on the binder. A double-action press or hydraulic press cushions may be required to achieve the necessary binder forces required to control sheet metal flow into the die cavity. Air cushions or nitrogen cylinders may not provide the required force for setting the draw beads or maintaining binder closure.

**Edge Cracking, Trimming, and Flanging.** The part and process thus needs to be designed to reduce stretch flangeability, because martensite and other hard phases reduce stretch flangeability (as noted in the section “High-Hole-Expansion (HHE) Steels” in this article). Local ductility, which is influenced by microstructure, affects stretch flanging and hole expansion. The edge condition after trimming is influenced by die clearance and wear. A clean edge cut is especially important for blanked or sheared edges and punched holes on AHSS material (Ref 12). A consistent and appropriate clearance is vital to minimize burr height. Cutting tools also need to be sufficiently sharp. Compared to sharp tools, worn tools result in a 20% reduction in hole expansion (stretch flangeability) in mild steels but a reduction of 50% or more in DP and TRIP grades (Ref 13).

Panels should be supported during trimming to eliminate the occurrence of bad burrs and to avoid edge cracking and tearing. This reduces the tendency for a bad burr, which in turn minimizes the tendency for edge cracking. Trim steels also need to be engineered with a higher strength in mind; the tensile strength of the AHSS grades can be substantially higher than that of conventional HSS (Ref 12). Abrupt changes in flange length act as local stress raisers that lead to edge cracks. Sharp notch features should be avoided in curved flanges. Flange die bend radii must be small in order to minimize springback.

In general, sheared-edge stretching limits are strongly related to the tensile strength, showing a significant decrease with increasing tensile strength for steels of tensile strength less than 700 MPa (102 ksi) and then saturating for steels of higher strength. Furthermore, during tool development, the blank die sometimes is the last one to be completed, necessitating the use of laser-cut blanks during prototype and even at the beginning of hard tool tryout. Laser-cut edges have much higher stretch flangeability than the sheared edge obtained from a conventional blank die, and as a result, tryout performance may be different (Ref 12).

**Springback.** As noted, springback is a function of the yield-strength-to-modulus ratio. Springback of AHSS grades is greater than that of mild steel or HSS, because of higher yield strength. The degree of springback correlates with yield strength after forming (rather than yield strength of the flat sheet). Thus, the higher strain hardening rate of DP and TRIP steels (Fig. 3) results in more springback than HSLA grades, even though the initial yield strength of the unformed blank may be similar.

Addressing springback requires careful assessment of both part and process design. Springback computer simulations should be

considered whenever possible to test process and design solutions (e.g., see the article “Computer-Aided Engineering in Sheet Metal Forming” in this Volume). Part and tool design should try to minimize springback effect rather than compensate for it. For example, springback can be reduced with sharper punch radii (Fig. 10). However, sharp radii may also increase forming challenges and press-load requirements. Sharp radii can contribute to excessive thinning, and stretch bending will be more difficult as yield strength increases.

Springback is a complicated problem. Its value depends on the nature of the deformation. Under certain conditions, the final bend angle can be smaller than the original angle, to give negative springback! Figure 10 is for simple bends, where the bar is held at one end and a bending force is applied to the other end. This figure is a plot of springback, defined as the percent change of curvature such that:

$$\text{Springback (\% change in curvature)} = \left[ \frac{1}{R} - \frac{1}{r} \right] \times 100 \quad (\text{Eq 3})$$

For a material that is perfectly plastic (i.e., it does not work harden), the previous equation under conditions of rigid springback (Eq 8 and 9a in the article “Springback” in this Volume) can be expressed as:

$$\text{Rigid-perfectly plastic springback} = \frac{3\sigma_0 R}{E \cdot t} \times 100 \quad (\text{Eq 4})$$

where  $\sigma_0$  is the tensile yield stress,  $E$  is elastic modulus, and  $t$  is thickness. A higher-order term occurs for elastic-perfectly plastic springback (Eq 12 and 13 in the article “Springback” in this Volume), but this additional term is not a

significant factor in the plot of Fig. 10 for a given yield strength.

However, it is very important to understand that this depends on how springback is defined. Springback does increase with  $R/t$  (Fig. 10) when springback is defined as a fractional curvature change. However, if springback is defined as a curvature change (not some fractional representation thereof), the opposite result is obtained, at least for the elastic-perfectly plastic case. In the article “Springback” in this Volume, the definition of springback is based on curvature change throughout.

Tool geometry also plays an important role in determining the resultant springback, because this affects the conditions of deformation. For example, if a very small amount of stretching is superimposed during bending, springback can be reduced or even eliminated. Under pure bending, springback is proportional to  $R/t$  for cylindrical tooling (Ref 15–17), U-bending/channel bending (Ref 18–20), V-bending (Ref 19–21), and flanging (Ref 22). However, under stretch-bending situations, it has been reported that springback decreased with increasing  $R/t$  in flanged channel (Ref 23) and draw bending (Ref 24).

In body panels, springback can be reduced by compensation through overbending of the flange. Guidelines for reducing springback in stamped components include avoiding right or acute angles, using larger open-wall angles, and avoiding large transition radii between two walls. Springback allowance must be increased as material strength increases: 3° for mild steels but 6° or more for HSS and AHSS.

**Wrinkling (Ref 12).** Although the benefit of the AHSS grades is the ability to reduce the sheet steel thickness, the decreased thickness has the potential to increase wrinkling if die clearances are not adjusted to reflect the reduced gage. Controlling the wrinkling requires higher press

**Fig. 10** Fractional change in curvature (springback) increased by yield strength (YS) and bend radius ( $R$ ) to sheet thickness ( $t$ ) ratio. Source: Ref 14

forces, which may lead to the need for higher-tonnage presses. The wrinkling, combined with the sheet steel overall strength, increases the potential for die wear. The high press forces can result in higher temperatures, which can cause lubricants to break down or burn, resulting in extreme wear conditions.

**Residual stresses** are induced in parts during their manufacture. Such stresses do not disappear when parts relax and all external constraints are removed. Some stamped parts produce significant residual stresses that create large springback when allowed to relax. Springback in a part results from stretch-bend forming. The stretch portion varies with the amount of the clamp force applied by the binder. Residual stress can cause distortion in stamped parts. It can be reduced in HSS stampings by proper part design and die-process planning. An effective way of reducing residual stresses is to use a die process where some form of post-stretch or shape-set may be required in order to induce a minimum of 2% stretch in the part near the bottom of the press stroke.

**Draw beads** control metal flow into the die cavity. Draw beads for HSS and AHSS should not extend around corners of the draw die, because this will result in locking out the metal flow and cause splitting in the corners of the part. Draw beads should “run out” at the tangent of the corner radius to minimize metal compression in corners, as shown in Fig 11.

**Tool Design.** The HSS and AHSS require a stiffer die to resist flexing that may lead to part distortions, especially for channel or hat-section parts. Tool geometry plays an important role in determining the final value of springback. As previously noted in the section “Springback” in this article, the influence of punch radii is different depending on the nature of the forming operation.

In pure bending, for example, springback decreases with increase in die radius because of diminishing bending forces in larger radii. In pure bending, the bending moment is inversely proportional to the radius of curvature, so that springback thus decreases with an increase in

radius of curvature (see, for example, Eq 6 in the article “Springback” in this Volume). This is true for fairly gentle radii (i.e.,  $R/t > 5$ ), where simple rules can be derived. Most sheet forming falls in this region. However, the trend reverses with very tight radii. The mechanics of very tight bending is complicated, so these results are mainly from finite element simulations using solid elements, which include three-dimensional states of stress and strain. Shell elements are not accurate in this region, and the simple rules do not apply.

In stretch-bend forming, springback (expressed as sidewall curl) is reduced by tighter tool radii (Fig. 10). Punch radii must be fairly sharp, approximately  $1t$  for HSS and greater than  $1t$  for AHSS. Many experiments and simulations show that the sidewall curl goes to nearly zero for  $R/t$  approximately equal to 2. In a series of stretch-bend tests of metal strips, the curl in DP 90 was removed when the specimen was drawn over a small radius ( $r/t < 1.5$ ) under high tension (Ref 26). The small radius is to pin the material and allow high tension to reduce springback.

**Die Processes.** The quality of stamped parts is critical in avoiding problems in assembly and in the final product performance. Quality problems may result from formability issues such as wrinkling caused by excessive compression or splitting caused by excessive tension, and from dimensional accuracy issues resulting from springback caused by elastic recovery. Controlling metal flow into the die cavity has been found to be crucial to both part quality and dimensional accuracy. Several alternate die processes for HSS are being evaluated. These are primarily focused on better process control and various means of inducing shape-set stretch in the stamping. Among these processes are programmable hydraulic blankholders for varying the force-stroke trajectory as the sheet is drawn, active drawbeads for increasing the restraining force as the press approaches bottom dead center, and flexible binder technology for local control of the binder area. In-process adjustment of the binder force can lead to better quality and improved part consistency. Mechanical presses

are being retrofitted with hydraulic multicylinder cushion systems to provide more control of the blankholder force during forming (Ref 25).

**Die wear.** High binder pressure is needed for stamping HSS and AHSS to maintain process control and to minimize buckles on the binder. Local contact loads can be very high for features with small radii. The higher compressive forces on the binder will require better die material, surface treatments, and lubricants. Tools must have sufficient toughness to avoid fracturing and good wear resistance for long-life operation and production reliability. Hard material coatings and nitriding have been used to improve the tribological properties of die surfaces. New developments in hard material coatings include advances in chemical vapor deposition, physical vapor deposition, and plasma-assisted chemical vapor deposition coatings. A new chemical vapor deposition coating has been developed to reduce abrasive wear during stamping of high-strength materials. It employs selective combinations of individual coating layers of titanium carbide (TiC), titanium carbonitride (TiCN), and titanium nitride (TiN) (Ref 27).

## Advantages and Disadvantages of Using HSS and AHSS (Ref 3)

The HSS and AHSS content in vehicles is expected to increase as more grades become commercially available and as new designs and manufacturing methods are developed.

Considerations should be taken as to whether a structure is designed to maximize strength or stiffness. For a constant modulus, component stiffness increases with increasing yield strength and sheet thickness. In a down-gaging strategy, HSS and AHSS will offer no advantage in improving stiffness, because all steels have the same modulus of elasticity.

Major advantages of using HSS and AHSS in automotive applications include potential for reducing vehicle weight, increased tensile strength, improved fatigue and impact strengths, and reduced material and transportation cost from weight reduction.

Major disadvantages of using HSS and AHSS include reduced stiffness due to thickness reduction, increased springback due to increase of flow strength, and limited formability due to low ductility. Also included are increased notch sensitivity, reduced dent resistance (when increase in strength cannot compensate for thickness reduction), and increased tool wear on the draw-die binder surfaces due to the high strength of these materials. However, tool wear can be reduced by upgrading tool materials and by applying protective coatings on the surface of the forming tools.

The implications of using thinner gages on the elastic stiffness and corrosion resistance need to be considered. Because the modulus of elasticity is the same for all steels, down-gaging reduces component stiffness. Also, because corrosion

**Fig. 11** Draw bead types showing conventional, run-out, and lock beads. Source: Ref 25

resistance of HSS and AHSS is similar to that of mild steel, thinner gages rust through faster under the same corrosion conditions.

Other concerns include weldability and paintability of such materials. Also, the effect of austenite-to-martensite transformation in TRIP grades on formability and process stability is yet to be determined.

# Forming of Steel Tailor-Welded Blanks\*

TAILOR-WELDED BLANKS consist of different types of sheet stock (with different thicknesses, grades/strengths, and sometimes coatings) that are welded together prior to forming. With variable-thickness blanks produced by welding together different sheet-stock combinations in specific regions, it is possible to make finished parts with a desirable variation in properties such as strength, corrosion resistance, and so on. In the automotive industry, for example, steel tailor-welded blanks are used to provide optimum strength using the least amount of material possible for specific points on a vehicle. By combining various steels into a single welded blank, product and manufacturing engineers can “tailor” the best properties of different steels so that they are located precisely within the part where they are needed.

Tailor-welded blanks are made from prime stock as nested blanks or from collectible offal. Although the tailor-welded-blank process was first developed as a method for utilizing collectible offal and improving blank nesting possibilities, its greatest potential lies in the area of blanks with different thicknesses, coatings, and material grades. Tailor-welded blanks give the product designer the opportunity to eliminate reinforcements while improving structural and dimensional characteristics.

Although tailor-welded-blank (TWB) technology with aluminum alloy sheet is an area of development, the main application is with steel TWB sheet for automotive components such as body side frames, door inner panels, motor compartment rails, center pillar inner panels, and wheelhouse/shock tower panels. The main benefit is weight reduction, which is derived from optimization of material and gage reductions in specified areas of the TWB and the finished part. In addition, the TWB process allows for part integration, eliminating the need for reinforcements and stiffeners (e.g., in situations when weight is reduced by using lighter-gage high-strength steel in place of heavier gage steels, leading to reduced structural stiffness). Material yield is also improved both by making use of collectible offal and by reducing offal as a result of a product design, thereby optimizing the material for the specific requirements of a given part. Overall, the benefits of steel TWB methods in automotive vehicles include:

- Fewer parts
- Fewer dies
- Fewer spot welds
- Reduced design and development time
- Lower manufacturing costs
- Reduced material use
- Optimization of the use of steel properties
- Weight reduction
- Improved dimensional accuracy
- Improved structural integrity
- Stiffness
- Improved safety
- Increased offal utilization and reduced scrap

This article briefly reviews the forming of steel tailor-welded blanks with some discussion of the effects of welding on forming. As with all stamping operations, control of the stamping operation for tailor-welded blanks requires monitoring parameters such as blankholder pressure, material uniformity, die gaging, lubrication, press tonnage, and overall process monitoring. This article is adapted from Ref 1 and covers weld factors (such as orientation of weld relative to metal movement in dies), the formability of TWB materials, die and press considerations, and specific factors for the drawing, stretching, and bending of steel tailor-welded blanks. Other product factors and process considerations are discussed in more detail in Ref 1.

## Welding Methods for Tailored Blanks

The types of welds that are used or have been considered for tailor-welded blanks include:

- Laser
- Resistance mash seam
- High-frequency induction
- Electron beam (nonvacuum)
- Friction-stir welding (more recently considered for aluminum TWB)

The type of weld joint selected for a specific application depends on a number of factors such as aesthetic and structural requirements, cost, and availability. Performance and the cost of welding operations are influenced by material handling and preparation, material gage, welding methods, overall blank dimensions, length of weld, and number and orientation of welds.

Currently, the most common methods of joining tailor-welded blanks are resistance mash-seam welding and laser welding. One of the earliest European applications of tailor-welded blanks for automotive applications was by Swedish carmaker Volvo using the resistance mash-seam process in 1979. An early use of laser-welded blanks in Europe was the Audi floor pan made by Thyssen A.G. in Germany since 1985. In North America, the initial use of tailor-welded blanks was on structural members such as frames, center pillar inner, and motor compartment upper rails. In the late 1960s, electron-beam welding was used by A.O. Smith to weld thicker gage (3.0 to 5.0 mm, or 0.12 to 0.20 in.) metal blanks for automotive frame members.

In Japan, welded blanks have been produced by laser methods both with and without filler wire by Toyota since 1986. Filler wire is used for applications that have an exposed weld in the finished product, such as body side frames. Filler wire welds are ground flush to improve surface appearance after welding. Welds that do not require a flush surface for aesthetic or sealing purposes are welded with Toyota's beam-weaving process (U.S. patent No. 5,245,156). Although beam weaving can reduce the concavity of the weld, it does not replace the filler wire process for body side frames, inasmuch as it does not satisfy the requirements for outer surfaces. Both filler wire and beam weaving are used to reduce the need for precision shearing and to allow laser welding of multipiece, multiweld blanks in a one fixture setup. By using die-cut blanks without precision shearing before each weld, Toyota eliminates the repeated processing steps of shearing and welding and the inefficient batch processing that is typical for multipiece, multiweld blanks being made on other welding systems.

## Selection of Welding Method

Tailored-blank welding processes have different capabilities that must be considered when designing a tailor-welded blank or selecting a welding process. For example, limits on length of weld and gage ratios are critical and influence the selection of an optimal welding process for

\*Adapted with permission from *Tailor Welded Blank Design and Manufacturing Manual*, Auto Steel Partnership Inc., July 1995; available from the Auto-Steel Partnership website: a-sp.org

a specific tailor-welded blank. Some processes have only straight-line capabilities, and edge-preparation is more critical with some processes than with others. The capabilities of various processes are summarized in Table 1. Figure 1 illustrates typical welding geometries, welds, and heat-affected zones for the various welding techniques.

**Laser beam butt welding** is a full-penetration fusion-welding process that results in a high depth-to-width ratio and therefore generally produces a narrow weld seam. Due to the extremely high cooling rate of the molten metal and narrow weld zone, the laser weld has a higher hardness than a resistance mash-seam weld. For laser butt welding, good edge preparation and beam alignment are critical to produce an acceptable weld.

For the laser-welding process, weld quality depends on parameters such as weld height, weld width, angle of surface alignment, mismatch, centering, and undercut or concavity (as defined from earlier testing of specimens). Similar tests and process controls can be applied to high-frequency induction and electron-beam welding processes. Postweld testing of laser or high-frequency-induction butt welds usually involves cup tests, dome tests, or hydraulic-bulge testing performed on randomly selected samples.

The laser beam tailor-welded blank has a butt-welded joint with a slight concavity at the joint with a narrower (about 1.0 mm, or 0.04 in.) heat-affected zone. Minimizing concavity of the weld joint is critical to good formability and mechanical properties. Minimum concavity in the weld joint is usually achieved by precision shearing the blank edges to be welded. A good fit-up prior to welding and proper laser-beam alignment with respect to the joint are important for a good laser weld. Other methods used to minimize concavity and reduce fit-up problems include the use of filler wire, beam weaving, beam orbiting, or beam spinning during the welding process.

Laser welding (Fig. 2, 3) using filler wire was developed by Toyota in order to increase the allowable gap of butt welding and to improve the weld appearance. This type of welding system does not require a precision sheared edge, but edge preparation is still a critical factor in producing a good weld. Cutting dies must be carefully maintained to produce an edge that is flat and straight, with minimum breakaway in order

to obtain a secure weld with minimum concavity. The use of filler wire also requires additional process controls for the wire feed and a postweld grinding operation of the excess filler material whenever needed by appearance or functional requirements.

Beam weaving also reduces the sharpness of the offset when welding different metal thicknesses (Fig. 3). The beam-weaving process

**Fig. 1** Welding geometries, welds, and heat-affected zones for the various welding techniques used to make tailor-welded blanks. (Values are typical for 1 mm, or 0.04 in., thick sheet and may vary depending on welding speed and power input.)

**Table 1** Capabilities of blank-welding methods

Capability	Process			
	Resistance mash-seam welding	Laser welding	High-frequency induction welding	Electron-beam welding
Straight-line capabilities	50 mm (2 in.) minimum and 2500 mm (100 in.) maximum weld length in a straight line only	About 3800 mm (150 in.) maximum weld length. The laser welding process can weld nonparallel lines using a multiaxis gantry robot system.	1 m (40 in.) maximum weld length	Weld length is limited only by size of blank-handling equipment. The electron-beam welding process can also make nonparallel welds. Because the beam location is fixed in the plan view, however, the X and Y axes must be on the table. For large blanks, this will result in a large shielding enclosure to allow room for the table movement.
Edge preparation	Edge preparation is unnecessary unless welding multiple-piece tailor-welded blanks, such as a body side ring.	Maintaining edge alignment becomes more difficult with longer welds (over 500 mm, or 20 in.). Therefore, edge preparation becomes more critical.	Edge preparation is not as critical as with the laser welding process.	Edge preparation is almost as critical as with the laser welding process.
Gages	0.7 mm (0.03 in.) minimum thickness 3 mm (0.12 in.) maximum thickness 5 mm (0.20 in.) total thickness (T1 + T2) 3-to-1 maximum material ratio	0.7 mm (0.03 in.) minimum thickness 3 mm (0.12 in.) is maximum thickness(a) 3-to-1 maximum material ratio	0.7 mm (0.03 in.) minimum thickness 2.5 mm (0.10 in.) maximum thickness 2.5-to-1 maximum material ratio	Minimum thickness is the same as for the laser case. 5 to 6 mm (0.20 to 0.24 in.) maximum thicknesses are possible(a).

(a) Depending on the maximum power capability with a 35 kW maximum for electron beam versus 8 kW maximum for laser. Electron-beam welding is not only faster than laser welding, but can also weld a thicker gage.

typically produces a wider laser weld (1.5 to 2.5 mm, or 0.06 to 0.10 in.), but reduces fit-up problems and concavity without precision shearing (for shorted welds) or the postweld grinding associated with filler wire. Use of the beam-weaving process makes beam alignment less critical in addition to reducing fit-up problems. As shown in Fig. 3, blanks can be aligned center-to-center or one-side flush. In either case, beam weaving will reduce the sharpness of the offset.

Blanks of different thicknesses are typically welded center-to-center to eliminate the need for right- or left-handed tools during the blank welding process. Blank stacks must be inverted for left-handed blanks. When appearance is important and weather-seal surface and wind-noise suppression are critical, the laser welding process may have advantages over the resistance mash-seam process due to surface geometry. Hem flange requirements may also favor laser welding.

**Laser Welding with Fixed Optics.** Laser systems with fixed optics are best for maintaining beam alignment and focus. This is a good process for two-piece tailored blanks with long welds, such as door inners and two-piece floor pans, but can require inefficient batch processing for multipieces moved under the fixed laser beam. Using a laser with fixed optics requires precision edge preparation before each weld. This requires a very large, multistage, dedicated system or an inefficient series of flexible systems for batch processing.

**Laser Welding with Moving Optics.** Laser systems with moving optics can be built in

single-axis or multiaxis configurations. This process can be used for multipiece, multiweld tailor-welded blanks in order to weld several pieces in one setup. A gantry robot can be coupled with the laser system to move the laser beam over a fixed workpiece. In addition to movement in the robot axes, the moving-optic system may include a reciprocating condenser lens that produces a beam-weaving effect along the weld path. This reduces the sharp offsets of heavier gages, slightly increases gap tolerances, and eliminates the need for filler wire or precision shearing before each welding operation.

**Resistance mash-seam welding** is a roller seam resistance-welding process that requires a small overlap (approximately 3 mm, or 0.12 in., depending on gage) with forging ("mashing") of the weld seam as the current is applied. Resistance mash-seam welding is thus a forging process that produces a solid-state weld. It is a relatively wide weld compared to the laser weld. Use of a resistance mash seam requires in-line welds for most efficient operation. For those welds that are not in-line, a retrim operation before the next weld may be required to ensure a consistent edge for the weld rollers. The result can be delays or make batch processing necessary.

Resistance mash-seam tailor-welded blanks have an overlap seam joint that is 10 to 50% thicker than the thicker of the joined materials and a heat-affected zone approximately twice the width of the weld. The reduction of thickness at the joint is limited by the necessity to avoid weld current shunting, depending on the gage of the materials. If the lap joint is deformed excessively during welding, shunts occur where the weld current can flow through a single thickness of material.

The thickened joint can be reduced to ~10% more than the thickness of the heavier-gage material by postweld planishing. The planishing process involves compressing the weld joint between steel rollers. This can be done immediately after welding at a temperature above

the recrystallization temperature (~550 °C, or 1000 °F, for sheet steel) as in hot planishing or after the weld has cooled via cold planishing. Hot planishing has better formability characteristics, but coated sheet steels can be a problem for this process due to coating pickup on the planishing rollers.

During the mash-seam welding operation, parameters such as voltage, amperage, temperature, and weld speed are monitored and recorded to ensure optimum weld conditions. Postweld testing of resistance mash-seam welds involves both cup testing for formability and peel testing for weld integrity. These are both destructive tests and are done only on random samples.

**High-frequency induction welding** is a butt-upset welding process. Volvo (with Elva Induction) developed this process for joining blanks. This type of weld has a thickening at the joint and a heat-affected zone similar in width to the resistance mash-seam weld. Grinding the joint can remove the thickened area to improve fit-up in assemblies. High-frequency-induction welding has a 1 m (40 in.) maximum weld length and ~50% thickening at the weld seam.

During the welding operation, the two blanks are pressed together edge-to-edge. They are held together by a clamp on each side of the joint over the full length of the weld. One clamp presses down on the fixed frame, while the other is pressed against the movable frame and follows its movement. The parts are in firm contact under fairly high pressure when the welding current is switched on. During welding, the edges are compressed by a certain amount. The material fuses without the use of filler material to a weld about 1 to 2 mm (0.04 to 0.08 in.) wide, depending on the thickness of the material. According to the developers, induction welding is considered to have a faster cycle time and lower operating costs than laser or resistance-mash-seam welding.

**Electron-beam (nonvacuum) welding** is also a fusion process. Power is typically in the

**Fig. 2** Laser welding using filler wire to make tailor-welded blanks and the resulting hardness distribution

	Weaving amplitude = 0 mm	Weaving amplitude = 0.5 mm	Weaving amplitude = 1.0 mm
Laser output: 3.5 kW Weaving frequency: 60 Hz			
Laser output: 5 kW Weaving frequency: 60 Hz			
Laser output: 3.5 kW Weaving frequency: 30 Hz			

**Fig. 3** Effect of laser power and beam-weaving amplitude and frequency on laser welds

25 to 35 kW range, making it a viable process for heavier-gage material. Compared to the laser welding process, electron-beam welding can tolerate a slightly larger gap between the edges to be welded. It is faster, and the beam is easier to focus. Although electron-beam welding offers some advantages over the laser-welding process, its use has been limited by radiation-shielding requirements to contain the x-rays generated by the process. The electron-beam welding process has been used by A.O. Smith to make tailor-welded blanks for heavy automotive frames, but is not being used in production currently. This type of weld is similar in appearance to a laser weld, but is about 50% wider.

## Special Considerations for Welding and Weld Design

**Blank Preparation Prior to Welding.** Most resistance mash-seam tailor-welded blanks have a die-cut edge at the weld seam. Butt-welding processes, on the other hand, require more accurate edge treatment. Long laser welds (>500 mm, or 20 in.) require a precision shearing operation prior to welding. The concavity of the laser weld is increased by excessive metal breakage at the trim edge. Some metal processors use long sections and “pocket” these sections during blanking (Fig. 4) in order to eliminate movement.

Short laser welds, electron-beam welds, and induction welds can be made with die-cut blanks if the dies are constructed to a standard similar to fine blanking. These standards demand more stringent tolerances than normal blanking dies. Die clearances that are normally between 6 and 10% of the sheet metal thickness must be reduced to a minimum, and holding forces on the pressure pads must be increased sufficiently to avoid recoil during blanking. This will reduce metal breakage and improve the fit-up at the weld joint. Also, the die shear must be increased to at least four times the metal thickness in order to reduce metal breakage.

Once the blank is trimmed, extreme care must be taken to not damage the edge to be welded. The blank must not be allowed to drop through the die nor down metal chutes or conveyors, and blank edges should not impact against stacker pins. Rather, each blank should

Fig. 4 Blanking-tooling design to ensure proper edge preparation for laser welding

be removed from the top of the die by vacuum cups or magnetic belts and placed on the stack with a vertical motion in order to avoid edge damage.

Die and press guidance is also critical. With the reduced die clearance, it is important to guide the die with oversize pins and bushings and run the die in a press with accurate slide guidance and parallelism.

**Pre- or Postweld Blank Washing and Lubrication.** Mill oils, dry lubricants, and other coatings can pose a problem for some welding systems, especially those that move the material with skew rolls. In such cases, blanks should be prewashed before welding in order to avoid slippage. It may also be necessary to reapply lubricants or to restore mill-applied prelube conditions to the finished blank after welding for formability and corrosion-resistance performance.

**Location of Welds Relative to Capabilities of Welding Equipment and Processes.** Straight-line welds for two-piece blanks can be made with most job-shop welding equipment, whether laser or resistance mash-seam. The main considerations for these types of welds concern limitations on length, thickness, formability, or aesthetics. Multipiece, multiweld blanks require careful planning to achieve economical production. These blanks often cannot be run in job-shop equipment without inefficient batch processing. Also, some weld orientations can cause efficiency problems in certain types of welding equipment (See Fig. 5).

High-volume blanks with multiple nonparallel welds and blanks with circular welds require more sophisticated welding equipment and processes. A gantry-mounted laser with three-axis capabilities and good edge preparation and clamping are necessary to accomplish this with a minimum amount of process steps and in a cost-effective manner.

Fig. 5 Preferred blank designs for resistance mash-seam or single-axis laser-welding systems

**Location of Welds in Blanks and Formed Parts.** Careful consideration should be given to metal movement in the forming dies when planning orientation of welds in the blank. The weld area and heat-affected zone reduce formability limits, and deformation transverse to the weld can result in failure in the base metal. Areas of excessive deformation in line with the weld are undesirable. For welds made from materials with similar thickness and strength, deformation transverse to the weld should not cause formability problems unless the weld is poor.

For welds made from materials with different thicknesses and/or strengths, failure normally occurs on the side for which the material is thinner or of lower strength because of the natural tendency for plastic flow to localize in weaker areas. For tailor-welded blanks made from materials of dissimilar thickness or strength, particular care therefore needs to be taken to minimize strength on the side with the greater thickness or higher strength. This can be accomplished by allowing greater material flow from the side of the weld with the greater thickness or higher strength by using less severe draw beads, reduced blankholder pressure, or modified blank outlines. Furthermore, blanks with significant differences in thickness or strength that could cause metal flow perpendicular to the weld seam may lead to excessive die wear and, if possible, should be relocated. Other measures to prevent die wear include the use of more wear-resistant die materials and die surface treatments and special die lubrications.

Areas that are subjected to bending and straight areas with minimal elongation are good choices for welds in line with metal movement. On the other hand, stretch flange areas (e.g., the inside corners of a body side frame such as corners of window or door openings) and deep-drawn areas with large elongation in the direction of the weld are poor places to locate a weld

joint. The flange edge adjacent to the weld is particularly susceptible to failure during stretch flanging (see Fig. 6). The reason for this precaution is because of the reduction in stretch flange capability in the area of the weld. Thicker/high-strength metal will tend to pull thinner/lower-strength metal during this type of deformation. Splitting usually occurs in the base metal or heat-affected zone beside the weld if weld lines are located in the stretch flange areas at the corners of these openings. Welds should not be located within 25 mm (1.0 in.) of an area subject to the biaxial strain of stretch flanging (see Fig. 7) without first determining the formability potential of the material through computer modeling.

**Postweld Blanking and Notching.** Use of square-sheared blanks for component blanks rather than pattern blanks usually requires postweld blanking for door and window parts. Square-sheared blanks allow the use of standard equipment such as square shears, trap shear lines, and oscillating cutoff dies. This type of standard blanking equipment is normally available at outside job shops. Such equipment, however, decreases material utilization because of inefficient nesting. It also increases the length of the weld.

Blanking dies for pattern blanks will not only improve material utilization but will also eliminate postweld blanking and shorten the length of welds because of the smaller blank size.

Postweld notching is used to remove a small area of imperfect weld at the end of some weld lines and to improve stress relief in stretch flange areas, as for the inside corners of body side frames. Postweld notching can be accomplished with a small hydraulic unit in line with the welder, instead of dies and presses. These units are similar to the units used for dimpling and embossing.

## Formability Considerations

Formability of tailor-welded blanks is an important consideration particularly in the weld area because of the heat-affected zone and hardening in the weld-joint region. Some of the important factors related to formability are summarized in this section. Additional information (for both steel and aluminum TWB formability) can be found in the Selected References cited at the end of this article.

**Formability tests for tailor-welded blanks** can be performed via tension testing (in line with

the weld and transverse to the weld) and by simulative forming tests. For example, a limiting dome-height test machine can be used to perform:

- Spherical-punch stretching tests (to simulate stretch forming)
- Hole-expansion tests (to simulate stretch flanging)
- Cylindrical contraction or cup-drawing tests (to simulate deep drawing)

These tests have shown that the most deleterious deformation modes for welds in tailor-welded blanks are plane strain (in line with the weld) and stretch flanging, especially with different metal thicknesses or strengths. With tailor-welded blanks that have different strengths or sheet thicknesses, the forming limit is further reduced as the strength ratio increases.

**General Formability Guidelines.** Early research on the formability of tailor-welded blanks (Ref 2) revealed important formability considerations for three standard forming operations: stretch forming, stretch flanging, and deep drawing. In stretch forming, it was found that the weld bead ductility is the limiting factor when the weld is oriented parallel to the major stretch axis, while the formability of the weaker base material is the limiting factor when the weld is normal to the stretch axis. It was also shown that stretch flangeability drops by 25 to 30% compared to the base material because of the presence of the weld, while deep drawability is unaffected.

Several subsequent investigations (Ref 3, 4) shed further insight into the formability of steel tailor-welded blanks. This work revealed that there is almost no difference in the formability of blanks made by resistance mash-seam and laser welding processes. Specifically, the tensile elongation in line with the weld is significantly

**Fig. 6** Factors affecting deformation and failure during stretch flanging of tailor-welded blanks

**Fig. 7** Difficult forming areas with respect to the placement of welded joints on tailor-welded blanks

reduced for blanks made by both techniques. Correspondingly, the limit strain can be reduced by more than 50%. For resistance mash-seam welds, the formability for as-welded blanks and as-welded blanks with hot planishing can be equivalent to laser-welded blanks of the same material combination. Cold planishing after resistance mash-seam welding, however, significantly reduces formability of the blank in the area of the weld.

It is important to note that tailor-weld blanks should only undergo deformation parallel to the weld line regardless of the global deformation mode. If strains perpendicular to the weld line exceed the thinning limit of the material, the result is failure parallel to the weld line of the thinner or lower-strength material. Thus, in the case of dissimilar blanks, the influence of geometry (i.e., thickness dissimilarity) generally outweighs differences in welding characteristics (see Fig. 8).

Additional formability studies on tailor-welded blanks performed at the Institute for Metal Forming at the University of Stuttgart (Ref 3) have shown that certain guidelines should be followed in the forming of welded blanks of different thicknesses. Because of the variation in the thickness of sheet steel, offset blankholder surfaces should be used in order to ensure a uniform surface pressure on the binder area of the drawn stamping. Furthermore, weld movement during the drawing process requires that the blankholder be designed with appropriate clearances in the region of the welds so that they can move through the area during the drawing process. These clearances, though necessary for movement of the heavier gage metal and the welds, can also be a source of wrinkling with lighter gages due to the lack of hold-down force in this area.

Another challenge with tailor-welded blanks is that due to the welding together of sheet segments with different thicknesses; different thickness variations within permitted tolerance ranges may have unfavorable effects on die performance. This is especially true in multigage blanks when the thinner material is at the lower gage tolerance and the thicker material is at the upper gage tolerance.

**Fig. 8** Deformation of weld line during drawing operation using blanks with dissimilar thickness

The formability of tailor-welded blanks has also been investigated at Ohio State University (OSU) (Ref 4). Failure of tailor-welded blanks is highly dependent on the amount the weld line moves. If the weld movement is too severe, the base material parallel to the weld line will tear. If the weld movement is not severe, the blank can either fail in the weld bead itself or in some other part of the blank, depending on the loading conditions. To evaluate the sensitivity of the weld movement to material and processing conditions, OSU conducted computer modeling. It was found that two conditions must be present for weld movement: a difference in the load-bearing capacity of the joined materials and stretching perpendicular to the weld. This combination forces the weaker material to deform, and the weld moves in the direction of the stronger material to compensate for it. If either a force normal to the weld is absent or if there is no difference in strength of the parent materials, no weld movement is observed. Hence, the severity of the weld movement is dependent on the strength ratio of the materials and the magnitude of the boundary forces. Computer modeling also indicated that weld movement is influenced to a much lesser extent by the global friction conditions, the local friction conditions in the weld area (especially for resistance mash-seam welds), the weld geometry, and the mechanical properties of the weld. When modeling the forming of a laser-welded blank, for example, the mechanical properties of the weld bead itself can be neglected with no significant loss of accuracy in the results. In order to predict the forming behavior of a tailor-welded blank, however, it is essential to have a clear understanding of the restraining forces around the edge of the blank. There were greater errors in model predictions due to discrepancies in the boundary forces than from the friction coefficient.

### Draw, Stretch, and Bend Considerations

In general, the performance of tailor-welded blanks during deep drawing is similar to the base metal unless stretching along the weld during drawing exceeds the forming limit of the weld. In this case, the stretchability of tailor-welded blanks is significantly less than the base metal. Stretching perpendicular to the weld normally does not cause any problems as long as the thinning limit of the weld material is not exceeded. On the other hand, a large amount of stretch in the direction of the weld may result in tearing across the weld line due to the poorer mechanical properties of the weld relative to those of the base material.

The formability of tailor-welded blanks depends on the type of welding, welding schedules, material, and thickness combinations. For a typical aluminum-killed drawing-quality (AKDQ) steel, for instance, the plane-strain forming limit can be between 15 and 20% for a

typical laser-welded blank and a resistance mash-seam blank with hot planish. To avoid splitting in the weld, the strain component along the weld line should be below the forming limit of the welded blanks.

In general, two types of splits may occur when forming tailor-welded blanks. One is across the weld, which can occur in blanks with similar-or-dissimilar thickness-or-strength material combinations. The other is parallel and immediately adjacent to the weld, which usually occurs in blanks made from materials with dissimilar thicknesses or strengths. To avoid splits in the weld, the weld should be placed away from the major strain direction and away from areas with high strains along the weld direction. The best orientation is placing the weld perpendicular to the major-strain direction. To avoid splits adjacent to the weld in the thinner gage or lower-strength material, the shift of the weld line from its initial position should be minimized. This may be accomplished by allowing more metal to flow from the binder surface on the thicker or higher-strength side of the draw die by reducing the severity of the draw beads, by reducing blankholder pressure, or by modifying the blank outline on the higher-strength or thicker gage side of the die. Another technique is to add a local nitrogen pad (such as a Teledyne DRAC system) along the weld line in order to minimize the weld-line shift.

Bending perpendicular to the weld line is normally not a problem. When bending on the weld and in-line with the weld, sharp radii should be avoided since severe bending will result in cracking or failure on the tensile surface of the weld in the bending area.

### Die and Press Considerations

Stamping presses must be equipped with tonnage monitors and strain gages in order to measure and record blankholder pressure and press tonnage. This is required for all stamping operations that bottom, such as draw dies and form dies. Pressure in each corner of the press can be optimized to suit the formability characteristics of the material. This tonnage must be determined and recorded at die tryout and maintained in each production run.

**Drawing dies.** Laser- and electron-beam-welded blanks of the same grade and thickness are not a major problem for drawing operations when the product planning and draw die development is done properly. As noted previously, it is important to minimize elongation in line with the weld and to avoid a stretch-flange condition perpendicular to the weld.

Resistance mash-seam and high-frequency induction tailor-welded blanks of the same grade require additional die clearance due to increased thickness at the weld line.

In all instances, careful planning for the weld-joint locations during product design and drawing-die development is necessary. Product design engineers and die engineers must work in

close collaboration during the development phase in order to achieve maximum cost effectiveness with the tailor-welded blanks. CAD/CAE software (such as ABAQUS, PMAS-TAMP, or DYNA3D) should be used to determine local deformations during forming.

Blanks of different thicknesses and strengths made with any welding process can pose challenges during die tryout and production because of the tendency for the elongation to be concentrated in the thinner or lower-strength material when deformation occurs perpendicular to the weld line. Also, when the metal-thickness difference is significant, press tonnage and balance can be a problem. Press-tonnage monitors are essential for this type of part, not only for protection of the press equipment, but also for good process control. If press balance is a problem, the tonnage monitors will indicate where the problem is. Supplemental balance devices, such as nitrogen cylinders, may be required in the die, or, in extreme cases, a larger press may be required.

Another consideration when planning blanks of mixed strength is that the die process for high-strength steel is often quite different than that for mild steel. High-strength steel can exhibit side-wall curl, springback, and drawability characteristics different from mild steel. Mild steel can usually be formed with high-strength-steel die processes, but high-strength steel will not always form satisfactorily with conventional-die processes. The use of developmental soft tooling is often advisable in such cases.

**Forming dies** require planning similar to draw dies. Elongation in line with and perpendicular to the weld must be considered before construction of hard tooling begins. Effects of different strengths and gages on formability and press tonnage and balance must also be evaluated. High-strength steel components in the welded blank require die technology and process planning suitable for this material.

**Trim Dies.** Trimming of stampings with major differences in metal thickness or strength

can cause press imbalance and excessive shock loads as the press energy is released when metal breakage occurs. Increasing the shear on the upper trim steel to four times the metal thickness per linear foot for high-strength steel will greatly reduce the shock loads. In extreme cases, nitrogen cylinders or urethane blocks may be necessary in the lower die to contain this sudden release of energy and reduce noise levels. Care must be taken during die construction to provide proper die clearance and shear for the different metal thicknesses in the stamping. As for forming dies, high-strength steel components in the welded blank require die technology and process planning suitable for this material (e.g., Fig. 9).

**Flanging Dies.** When flanging material of different strengths, springback allowance must be made for the higher-strength material. This means that a panel setup that allows a wiping action (where the flange surface is vertical or perpendicular to the die surface) on flanges of the higher-strength material will result in a bumping action (where the flange surface is struck home to an open angle when the press is on bottom dead center) for the lower-strength material, which requires less overbend for springback. Usually, this difference will be no more than three degrees, but could be more for some higher-strength steels.

Stretch flanging operations must be designed carefully with respect to the placement of the weld joint and when using high-strength steels. Weld placements that should be avoided are illustrated in Fig. 9; the flange length for high-strength steels in these areas should be limited.

**Hemming Dies and Hemming Machines.** Hemming over different metal thicknesses on an inner panel can present a challenging quality problem for outer panel surface with respect to hem radius uniformity. In such cases, a simple yet effective course of action for door assemblies is to make the metal thickness transition as gradual as possible by coining the thicker portion of the hem surface on the inner door panel adjacent to the weld in one of the form dies.

This will reduce the abrupt transition from the thicker material to the thinner gage.

Another consideration is the type of hemming operation and its effect on surface and hem-radius quality. Hemming can be done in mechanical or hydraulic presses with separate prehem and finish-hem dies or a two-stage hem die. Also, hemming machines with hydraulic, pneumatic, or electric drives have been used. In order to ensure the best surface and hem radius quality, a process with a controlled pressure is necessary. This requirement excludes any hem operation in a mechanical press that will hem by hitting solid at the bottom of the press stroke. A process that flattens the hem with a squeezing action is preferred. In addition, the prehem and finish hem should be completed in one tool to avoid mismatches in the outline. Hemming fixtures or dies in hydraulic presses can produce the desired results if constructed with proper gaging and cam designs or mechanical linkages for effective prehem and final-hem actions.

# Press Forming of Coated Steel

Revised by Brian Allen, AK Steel Corporation

COATED FLAT-ROLLED STEELS are formed using the same general equipment, tooling, and lubrication used to form uncoated steels. While the properties of the base steel remain the primary determinants of the formability of a coated product, coatings do have an effect on the forming process and must be taken into account when designing parts, dies, and forming strategies. Not only do the surface coatings affect the lubricity at the die/part interface, the forming process must be carried out in such a way as to maintain the coating integrity and preserve the original purpose of the coating.

Most coatings commonly used on sheet steel substrates have corrosion resistance as their primary function, although appearance is often important as well, especially for the organic coatings. Coatings can have a different coefficient of friction with common die materials than the steel substrate and may be more ductile or more brittle than the base metal. Various coatings also react differently with different lubricants and die materials than bare steels. Given the friction and formability differences between steel substrates and common coating materials, some adjustments to the forming process are usually necessary to obtain optimal results when switching from bare to coated steels or when changing coatings. While coated steels can usually be successfully formed on tooling designed for bare steel, part cost and quality improvements can frequently be realized if tooling, lubrication, forming parameters, and part geometry are adjusted to suit the coating/substrate combination being used.

Because most coatings are softer than the steel substrate, steps to protect the coating from damage are sometimes necessary. Coating damage can take place in the die but also occurs during blank or part handling, especially if sharp edges or burrs on blanks or formed parts are allowed to rub or scrape against adjacent pieces during stacking or handling. The brittle nature of some coatings may impose forming path or bend radii limits on coated steels that are much more stringent than would be the case with bare steels. These limits must be observed not only in the finished part but also in all areas of the part, including drawbeads and other areas outside the final part shape. Even if coating damage to the material outside the part trim line is acceptable

from a part quality perspective, coating scraped or flaked off the part scrap will build up in the tooling and eventually result in dents, defects, or increased downtime and labor for die cleaning.

This article provides a general overview of some of the more common sheet steel coatings available. It also discusses formability differences between coated and bare steel and provides some general guidelines about the forming of coated steels. Information on the forming of uncoated steels can be found in other articles in this Volume.

## Coated Steels

Coated steels are classified according to the nature of the substrate, the type of coating, and the method used to apply the coating. Nearly every type of sheet steel commonly used in the automotive, appliance, or building industries is available coated, from high-strength steels used for automotive structural members, steel roofing, and architectural framing, to vacuum degassed interstitial-free steels used in applications demanding the highest available formability. The types of substrate steels available are discussed in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1, ASM Handbook, 1990.

Common steel coatings include zinc, aluminum, tin, lead, nickel, and various alloys of these metals, as well as a range of organic coatings. Coatings such as porcelain enamels and electroplated copper or chromium are also commonly found on sheet steel parts, but these are typically applied after forming and are not discussed here. Most sheet steel coatings are applied for purposes of corrosion protection, but some coatings, particularly the organics, are also applied for aesthetic reasons. Application methods vary widely and include dipping in a molten bath (zinc, aluminum, tin, and terne—a lead-tin alloy), electroplating (zinc and tin), and spraying or roll coating (paints or organics).

**Die Interaction Effects.** The interaction between die materials and coatings is very complicated and should be considered when switching from bare to coated steels, when switching lubricants, or when developing new parts using prototype tooling. Both electro-

galvanized and galvanized steels have been shown to be sensitive to changes in tooling material between gray cast iron, nitrided gray cast iron, torch-hardened cast iron, bare steel, TiN-coated steel, and CrN-coated steel (Ref 1).

Galvanized steel performed best with gray cast iron (GCI) tooling, followed by torch-hardened GCI and nitrided GCI. Electroplated steel performed best in TiN- and CrN-coated dies, followed by bare steel and nitrided GCI dies. Cold rolled steel was only slightly sensitive to tooling material changes, and hot dip galvanized material was relatively insensitive to tool material. Coated steels were also observed to have a higher sensitivity to lubricant changes than were bare steels. For the two lubricants used in the referenced study, electroplated sheet was found to be the most sensitive to lubricant change, followed by galvanized, hot dip galvanized, and uncoated steel.

Coated steels may also show different behavior than cold rolled steels when switching from zinc-base Kirksite or other types of soft tooling prototype dies to hard production dies (Ref 2). Higher punch loads have been noted on a Kirksite prototype die as compared to the hardened-steel production die for cold rolled steel, while electroplated steel showed the reverse trend. The punch load was also found to be more sensitive to punch speed when forming electroplated steel as compared with uncoated steel for both die materials (Ref 3).

## Zinc-Coated Steels

By far, the most widely used steel coating applied prior to press forming is zinc. Zinc coating is usually referred to as galvanizing, after the galvanic corrosion protection provided to the steel substrate by the zinc coating. Zinc coatings are applied to the strip via electroplating or by immersion of the strip in a bath of molten zinc. Both methods are common, but the hot dip coating is more prevalent.

## Hot Dip Galvanizing

Hot dip galvanizing is conducted using one of two processes. Historically, most hot dip

galvanized material was batch annealed in coil form, then processed on a flux line, where it was unwound and passed through a series of cleaning and fluxing or pickling tanks for removal of any oxides or other surface contamination prior to entry into a molten zinc bath. Today, most material is processed on continuous annealing lines, where coils of cold rolled material are fed through an atmosphere-controlled, in-line annealing furnace designed to both anneal the strip and burn off or reduce any oils, contaminants, or surface oxides that may be present. The strip passes from the continuous annealing furnace through a controlled cooling section, which reduces the strip temperature to molten zinc levels, and enters the bath through an inert-gas-filled snout submerged in the liquid zinc.

On emergence from the zinc bath, the strip passes through two blowoffs, or air knives, where the thickness of the still-molten zinc is controlled by varying the air pressure fed to the knives. On-line measurements of the coating thickness provide feedback control to the wiping system, allowing continuous monitoring and control of the amount of zinc being deposited on each side of the strip. Coating thicknesses on each side of the strip are typically kept equal but may be varied independently to some extent. One-side-only coatings are not feasible via the standard hot dipping process. Procedures to remove the semisolidified zinc on one side of the sheet via brushing or other physical methods have been developed but are not widely used.

Steel processing is typically complete after cooling and a temper rolling operation designed to eliminate discontinuous yielding, which would otherwise result in objectionable stretcher strain lines (Lüders bands) in the formed parts. Most modern hot dip galvanizing lines incorporate inline temper rolling, but off-line temper rolling or stretch leveling may also be used. In some specialized instances, the coated steel coils can be low-temperature batch annealed after hot dip coating to further alter the mechanical properties of the strip. However, due to the relative cost of the additional annealing operation, steels are designed to meet the final specifications directly off the galvanizing line, if possible.

**Formability Considerations.** At molten zinc temperatures, zinc and iron react, forming a series of intermetallic compounds with varying iron-to-zinc ratios. This reaction results in an alloy layer between the steel surface and the molten zinc, the thickness of which depends on the time and temperature profile of the coating process as well as the alloy composition of the steel substrate. The rate of the reaction is highly dependent on the presence of intentional alloy additions and unavoidable impurities, particularly lead and aluminum, which are present in the zinc coating bath. Because this alloy layer is significantly more brittle than either the zinc coating or the steel substrate, the degree of forming a coated steel can withstand prior to coating flaking is reduced as the thickness of the alloy layer increases. Steel producers strive to

minimize the thickness and alter the phases present in the alloy layer to mitigate the effects that the brittle iron-zinc intermetallics have on the subsequent formability and coating adhesion of the material.

Given proper tooling and press setup, the layer of free zinc on the surface of the steel substrate can result in an increased formability of hot dip galvanized steel over bare sheet, particularly in deep-drawing operations. The soft zinc on the tool surface prevents direct contact between the steel substrate and the punch or die, thus eliminating galling between the two steel surfaces and resulting in increased draw depths.

**Typical Products.** Hot dip galvanized coatings are readily available on all standard and most proprietary grades of sheet steels. Common ASTM and SAE steel grade designations include:

- Commercial steel (QS)
- Drawing steel (DS)
- Extradeep-drawing steel (EDDS)
- Extradeep-drawing steel plus (EDDS+)
- Structural steel (SS)
- High-strength low-alloy steel (HSLAS)
- Dent-resistant steel (DR)
- Bake-hardenable steel (BH)

Thickness of the zinc coating is typically specified by coating weight per surface area in the units of grams per square meter, with typical commercially available thickness ranges starting at 20 g/m<sup>2</sup> (0.07 oz/ft<sup>2</sup>) and ranging up to 600 g/m<sup>2</sup> (2.0 oz/ft<sup>2</sup>). Zinc coating weight is also occasionally discussed in terms of coating thickness, with the aforementioned coating weights correlating to coating thicknesses of 2.8 to 84.0  $\mu$ m (0.0001 to 0.0034 in.).

Good coating thickness control is particularly important in parts that will be assembled or affixed by welding, because small variations in zinc thickness can have an appreciable impact on the welding parameters needed to achieve high-quality welds.

**Tool Design.** Tools for forming galvanized steels are manufactured from the same materials as tools used for bare steel. Springback compensation is based on the strength and properties of the base metal and is not appreciably affected by the zinc coating. As hot dip coating is applied to a wide range of steels, from the most formable interstitial-free grades to very high-strength dual-phase and transformation-induced plasticity steels, the primary consideration when designing forming tools for a galvanized steel is the base metal. The effects of the zinc layer on formability are small compared to the effects of the base metal and stem primarily from the soft nature of the coating and the presence of the brittle intermetallic layer that may exist in varying levels of severity between the coating and the substrate.

Galvanized coatings will typically stand tensile strains that result in failure of the base metal without flaking, but compressive strains are much more damaging to the brittle iron-zinc intermetallic alloy layer. Under moderate tensile

strains, the thin intermetallic layer cracks but does not lose adherence with the steel substrate. The ductile zinc layer bridges these cracks in the alloy layer, and no loss of coating integrity results. During compression, the alloy layer not only cracks, but also the compressive stresses can cause portions of the coating to wedge against each other. Even in this state, coating adhesion is typically adequate, but if the compressive strains are followed by further tensile strains, the fractured alloy layer is unable to maintain cohesion with the substrate, and large particles of the coating may flake off. Figure 1 schematically illustrates the process.

Excessive coating loss typically requires a compressive strain, followed by a tensile strain in the same direction. Most zinc adhesion issues in hot dip galvanized steels occur when material is pulled over a sharp radius, then stretched in tension. As the material flows over a sharp radius, a high compressive bending strain is imposed on the coating on the inside diameter (ID) of the bend. As the material flows off the bend, it is straightened and placed in tension. This sequence of events occurs on the outside diameter (OD) of a drawn cup, explaining why coating adhesion problems are typically worse on the OD than the ID of a drawn cup. As the blank flows into the die, the material on the cup OD is compressed as it bends to flow over the die radius, then is straightened and stretched as it moves into the sidewall of the cup. The material

**Fig. 1** The effects of tensile and compressive strains on the alloy layer of hot dip galvanized sheet steels

on the cup ID remains in tension, both when being drawn in the die and when being stretched in the cup sidewall. Adhesion can be improved by reducing the compressive stresses via an increased die radius or blankholder force or by decreasing the subsequent tensile stresses by limiting the draw depth of the cup.

Pulling material through an excessively small radius or across a sharp drawbead not only affects coating adherence but can result in scoring of the soft zinc or, in extreme cases, the shaving of flakes of zinc from the surface. This not only results in a cosmetic defect but also reduces the corrosion protection of the finished part. Zinc particles removed from the steel surface can build up in the press or die and cause dents, buildup, and numerous other problems.

The soft zinc coating can also be easily damaged during forming and handling operations. Thus, dies used for galvanized material must be kept free of damage or rough spots that could impart scratches and other cosmetic marks to the soft zinc coating. Sharp burrs on sheared edges can easily cause objectionable coating marks, especially if the blanks or formed parts are slid against one another during stacking, handling, or assembly. The degree of effort necessary to prevent these defects depends heavily on the nature of the part, the manufacturing process, and any secondary finishing or coating operations.

If there are no severe radii in the part or excessively sharp corners over which metal is forced to flow, most tools designed for bare steel can be used for coated sheet. Due to variances in coatings, thicknesses, and lubrication, there are no definitive radius limit guidelines, but in general, radii over which material is being drawn should be made as generous as possible. Simple bending is less of an issue, because the compressive-to-tensile strain reversal that is most damaging to the coating is not encountered in a simple bend. Table 1 shows radii minimums for simple bending. Radii over which material is pulled should be significantly more generous than radii for simple bending. Few problems should be encountered as long as dies are kept polished enough to prevent damage to the soft

zinc surface and radii are kept large enough to avoid severe fracturing of the brittle iron-zinc intermetallic layer due to compressive bending stresses.

### Electrogalvanizing

Electrogalvanized steels are produced by batch annealing the cold rolled steel in coil form, temper rolling, then electroplating a layer of essentially pure zinc crystals on the surface of the sheet. As with hot dip galvanized products, the zinc coating is much softer than the base steel and can help provide some lubricity in forming, especially in preventing galling during deep-drawing operations. Because the electrocoating process is not conducted at elevated temperatures, the brittle iron-zinc intermetallic layer that sometimes imposes forming limits on hot dip galvanized steels does not form between the base steel and the coating. Therefore, the forming limits on electrogalvanized material are very similar to those of the bare substrate. Similar care must be taken to avoid rough spots in dies and burrs on blanks or finished parts, which could damage the soft zinc layer during forming or part handling.

Electrogalvanized coatings are typically much thinner than hot dip coatings, generally ranging from approximately 20 to 100 g/m<sup>2</sup> (0.07 to 0.33 oz/ft<sup>2</sup>). These coating weights correlate to coating thicknesses of 2.8 to 13.5 µm (0.0001 to 0.0005 in.).

Like hot dip galvanized material, electrogalvanized material can be supplied with different coating weights on each side of the material. Unlike the hot dip process, electrogalvanized material is commonly supplied "one side only," where one side of the material remains bare. Because of the galvanic nature of the corrosion protection, the zinc coating on one side of the sheet will still provide corrosion protection for the bare side.

### Zinc-Nickel

A 10 to 14% Ni addition can be made to the zinc electroplated on the steel substrate to provide an electrogalvanized zinc-nickel alloy coating. The nickel addition is used primarily to improve the corrosion resistance of the coating, but it also dramatically increases the coating hardness. Typical applications include fuel tanks and other automotive components. The increased hardness results in a reduced coefficient of friction at higher coating nickel contents. Nickel contents above 15% are not used because the corrosion resistance of the coating begins to decrease at higher nickel levels, and the interfacial shear strength of the coating to the base steel falls below acceptable levels. Weight loss due to coating exfoliation on a drawn cup has been shown to increase dramatically for coating nickel contents over 12% (Ref 5). The higher coating hardness helps limit coating damage, and the lower coefficient of friction may help

improve formability by helping to distribute strain more evenly. However, at higher nickel levels, part radii may be limited by coating adherence.

Electrogalvanized zinc-nickel coatings can be applied to any steel that can be electrogalvanized, but availability is limited due to a limited number of suppliers and a limited demand.

### Galvannealed Steels

Galvannealed steels are hot dip galvanized steels that are given a secondary heat treatment after zinc plating to alloy the zinc coating with the base steel. The resulting iron-zinc alloy coating typically consists of a thin layer of FeZn<sub>4</sub> (gamma) at the interface, with the bulk of the coating consisting of FeZn<sub>7</sub> (delta). Crystals of FeZn<sub>13</sub> (zeta) frequently exist at the surface of the coating. Producers generally try to avoid the formation of excessive amounts of zeta phase, because the softer, blocky zeta crystals have been shown to increase friction, with the associated reduction of formability (Ref 6).

The intermetallic galvanneal coatings are specified because of their advantages with respect to welding and paint adhesion. The coating is harder than pure zinc, so it is more resistant to scratching and handling damage, but it is brittle and therefore much more prone to exfoliation during forming.

Coating exfoliation in galvannealed sheet steels takes place by one of two mechanisms: powdering or flaking. Powdering occurs due to cracking in the delta layer of the coating, causing the coating to exfoliate in small, generally equiaxed particles with diameters less than the coating thickness. Flaking is primarily caused by fracture of the gamma layer at the steel/coating interface and results in flakes of material with a thickness equal to the coating thickness and a diameter much larger than the coating thickness.

Powdering has been shown to result from excessively tight radii in the part itself or at the draw bead. The brittle coating cannot deform in tandem with the base steel and cracks to relieve the stress. The level of this cracking is related to the amount of surface strain in the part; thus, tighter radii result in increased coating cracking and increased powdering (Ref 7, 8). The ID radii are more prone to powdering than the OD radii, because the compressive stresses force the fractured coating pieces together and tend to wedge many of them up and break them free from the coating. Powdering is not generally severe enough to cause corrosion or cosmetic problems on the sheet itself, but the buildup of coating powder in the dies can quickly result in dents and other problems on formed parts, increasing scrap rates and necessitating frequent line shutdowns and increased die cleaning.

Flaking is more predominant where coated sheets are slid against a die under high speed and/or high pressure, such as would occur during an ironing operation. Higher pressures and forming

speeds increase flaking, presumably due to frictional and heat effects that create shear forces exceeding the shear strength of the gamma layer at the steel/coating interface (Ref 9). Figure 2 shows a schematic of this process.

### Electrogalvannealed Steel

Galvannealed steels are also produced by electroplating the zinc-iron alloy directly onto the surface of the strip, similar to the way zinc-nickel electrogalvanized coatings are produced. The electroplated galvanneal coating contains the same phases as a hot-dipped and furnace-alloyed galvanneal coating, but the phases in the electroplated coating are uniformly and homogeneously distributed as opposed to the layered structure that develops in the hot dip galvannealed process. This coating homogeneity, combined with the lack of a continuous gamma layer at the steel/coating interface, results in a significantly higher resistance to powdering and flaking in the electroplated coating as compared to the furnace-alloyed coating (Ref 10).

### Aluminum-Coated Steels

Hot dip aluminum-coated steels (aluminized steels) are used in applications requiring greater

**Fig. 2** Schematic of the powdering and flaking of galvannealed coatings on sheet steels. OD, outside diameter; ID, inside diameter

salt spray or atmospheric corrosion protection than is offered by zinc-coated steels. The aluminized coating also provides corrosion protection at maximum temperatures that are significantly higher than those available with zinc coatings, making aluminized steel the material of choice for mufflers, heat exchangers, and many other parts that must exhibit both good corrosion resistance and high-temperature stability of the coating.

Aluminized steels are formed using the same general practices as are used for forming bare and zinc-galvanized sheet. There are two types of aluminized coatings commonly used on carbon and ferritic stainless steels, referred to as type 1 and type 2. Type 1 is an aluminum-silicon alloy with a silicon content from 5 to 11% used primarily for high-temperature applications. Type 2 is a commercially pure aluminum coating used for resistance to atmospheric corrosion. The

rapid reaction of iron with molten aluminum at hot dip coating temperatures results in a relatively thick  $\text{Fe}_2\text{Al}_5$  iron-aluminum intermetallic layer at the steel/coating interface. This brittle adhesion layer is typically the limiting factor in the formability of both types of coatings, with excessive forming severely damaging the alloy layer and resulting in coating exfoliation.

The addition of silicon to the molten aluminum coating bath reduces the required bath temperature and inhibits the growth rate of the intermetallic layer. Both of these effects retard the formation of  $\text{Fe}_2\text{Al}_5$  at the steel/coating interface, resulting in a thinner and smoother intermetallic layer. This alloy layer difference causes the type 1 coating to have better adhesion and higher forming limits than the type 2 coating. Micrographs showing the alloy layer differences between typical type 1 and type 2 coatings are displayed in Fig. 3. Precise formability limits of the coated steel are difficult to characterize, because alloy layer thickness and properties vary from product to product, being highly dependent on substrate chemistry, overall coating thickness, bath composition, bath temperature, and several coating line parameters. Because adhesion of aluminized coatings is primarily dependent on alloy layer thickness, thicker coatings, which have a thicker alloy layer, will exhibit lower coating adhesion than thinner coatings.

Formability limits are sometimes controlled by the required corrosion resistance of the part being formed. Hairline cracks that develop in the coating during forming can limit the corrosion resistance of the coating, even if no visible coating damage develops. Table 2 shows the effects of coating thickness on the atmospheric corrosion resistance of type 1 and type 2 aluminized coatings of varying thicknesses.

While sufficient tensile strains will cause coating cracking that may impact corrosion resistance, tensile stresses alone will rarely result in extensive coating exfoliation. Even coatings with excessively thick alloy layers will typically not exhibit any coating peeling in tension, even if strained up to the point of base metal fracture, as long as no compressive stresses have been previously applied. Tensile forces will cause the

(b) Type 2 coating forms a layer of essentially pure aluminum (top) with scattered gray particles of aluminum-iron; the light-gray center layer is aluminum-iron, and the bottom layer is the base steel. Original magnification for both 1000×

**Table 2** Minimum simple bend radii for corrosion-resistant 180° bends in various thicknesses of aluminized sheet steels

Steel sheet thickness (t)		Minimum bend radius	
		Type 1 coating(a)	Type 2 coating(b)
mm	in.		
1.61	0.0635	1.5t	2.5t
1.31	0.0516	1.5t	2t
1.00	0.0396	1.5t	1.5t
0.85	0.0336	...	1t
0.70	0.0276	0.5t	0.5t

(a) Coating containing approximately 9% Si and weighing 150 g/m<sup>2</sup> (0.5 oz/ft<sup>2</sup>). Minimum radii are for no rust on the outside of the bend after exposure to air for 25 cycles consisting of 30 min at 595 °C (1100 °F) and 30 min of cooling. (b) Coating of commercially pure aluminum weighing 350 g/m<sup>2</sup> (1.15 oz/ft<sup>2</sup>). Minimum bend radii are for no rusting at the outside of the bend after 1 year of exposure to a mild industrial atmosphere.

brittle alloy layer to crack, but the high ductility of the aluminum coating allows the outer layer of the coating to elongate and provide unbroken coverage to the underlying steel.

Compressive stresses cause the alloy layer to fracture and wedge up but do not typically result in coating exfoliation unless a tensile strain is subsequently applied. Compressive strains followed by tensile strains, such as occurs on the OD of a drawn cup, are most damaging to the coating. In cup drawing, as the material flows into the deep-drawing die, the material on the OD side of the cup is placed in compression as it bends over the die radius. As the material flows into the wall of the cup, it is unbent and stretched in tension, sometimes resulting in coating loss. The process is identical to that illustrated in Fig. 1 for hot dip galvanized steels. The extent of coating damage is dependent on the levels of compressive and tensile strain applied. Coating exfoliation has been shown to increase dramatically on the OD of deep-drawn cups as coating compressive stresses are increased by reducing the die radius. Coating damage was prevented by providing a large enough die radii to reduce coating compressive stresses to acceptable levels (Ref 11).

In most stamped parts, the majority of the part is in tension, and therefore, coating peeling is not a danger. The potential problems come from areas where material is first pulled through a drawbead, forcing one side of the coating into compression, then subsequently strained in tension. Eliminating drawbeads wherever possible may improve coating adhesion, but the increased binder force required will increase the potential for coating scratches or gouging and may require higher levels of binder maintenance. Type 1 coatings are harder than type 2, but all aluminum coatings, such as zinc, are softer than the underlying steel substrate so require the same additional care to avoid cosmetic damage to the surface of the coating.

**Aluminum-Zinc Alloy Coatings.** Two types of aluminum-zinc alloy coatings are generally available: one consisting of approximately 45% Zn and 55% Al, the other consisting of 5% Al with the remainder zinc. Both types of coatings frequently contain other alloy additions designed to improve strip wettability during coating and to help limit the growth of any brittle intermetallic layers at the steel/coating interface.

The 55% Al coating has a superior atmospheric corrosion resistance to pure zinc coatings while retaining enough galvanic corrosion protection to eliminate rust staining at sheared edges, screw holes, or other minor coating breaches. The primary use of this material is in roofing and other architectural panels, but it also finds applications in the appliance and automotive markets. The heat resistance of the alloy coating is intermediate to the pure zinc or aluminum coatings, while the formability is similar to a hot dip zinc-galvanized product.

The 5% Al coating has a slightly higher atmospheric corrosion resistance than zinc-galvanized material. Its primary advantage is a

slightly improved resistance to cracking during forming (Ref 12), which makes it attractive for the manufacture of deep-drawn parts.

## Tin-Coated Steels

Tin-coated steels are extensively used in the food packaging industry but also find applications in the hardware, appliance, automotive, and kitchen equipment industries. Almost all tin-coated steel is produced using an electrocoating process, although tin can be and sometimes is applied by hot dipping. Electroplated tin is typically applied in a thickness range of 0.4 to 2.3  $\mu\text{m}$  (0.02 to 0.1 mil); hot-dipped product is typically 1.5 to 2 times thicker. As with the zinc- and aluminum-coated steels discussed previously, the soft, ductile tin coating helps to increase die life and reduce lubrication requirements as compared to bare steel. The main difference between tin and hot-dipped zinc or aluminum is that tin, even hot dipped, usually does not develop an alloy layer of any appreciable thickness between the coating and the substrate. Thus, the formability of tin-coated steels is limited only by the formability of the base metal. Coating powdering, flaking, and decohesion are not typically factors of concern. The high lubricity of the tin coating results in a significantly improved drawability of tin-coated steels as compared to bare steels.

The tin coating is much softer and more easily damaged than the surface of the steel substrate, so all of the warnings against cosmetic coating damage from rough spots in dies, burrs, or sharp edges of adjacent parts or blanks typically given for galvanized or aluminized steels also apply to tin-coated steels.

## Terne-Coated Steels

Terne coat is a lead-tin alloy coating that typically contains 10 to 25% Sn by weight. Terne coating is used where low cost and good atmospheric corrosion resistance are necessary. It finds applications in roofing, architectural items, and automotive fuel tanks. The toxicity of the lead component of the terne coating is an environmental concern, and the use of terne coatings has significantly declined in recent years. Terne coatings will probably be totally phased out in the near future.

The properties of terne-coated steels are very similar to those of tin-coated steels. Like tin, terne coatings do not develop any significant brittle alloy layer between the base steel and the ductile coating. Thus, the coating does not limit the formability of the base steel, and the lubricity increase over bare steel may even result in increased formability of terne-coated steels. Like most other coatings, terne is much softer than the underlying steel, and some precautions must be taken to prevent coating damage.

## Nickel, Copper, and Chromium Plating

Decorative items are sometimes made from steel that has been electroplated with nickel, copper, or chromium, but typically these coatings are applied to finished parts after forming. Due to the limited amount of forming done on steels coated with these materials, they are not covered in depth here.

## Organic-Coated Steels

Typical organic coatings applied to steels prior to forming include several classes of paints and plastic coatings. While most organic-coated parts are coated after forming, parts can often be successfully formed from steel coated in the coil form at a significant cost advantage over parts painted after forming. Precoated sheet steels are formed using processes and equipment similar to those used in forming cold rolled steel. Most standard grades and gages of flat-rolled steel can be purchased with any of a variety of organic coatings available from multiple suppliers.

Tooling used for cold rolled steel is usually suitable for forming organically coated steels, although the less abrasive surface presented to the tool by the organic coating frequently allows forming tools to be manufactured of lower-strength, softer, and less shock-resistant materials. In appearance-critical applications, rubber or plastic die inserts are sometimes used in select areas of the die to help prevent coating damage during forming.

Organic coatings are much more susceptible to scratching and other surface damage than cold rolled or galvanized steels. To avoid scoring or scratching the organic coatings, die surfaces must be highly polished and kept free of burrs, or rough spots. Blank and part handling is critical to avoid damage to the coating caused by foreign particles, burrs, or the edges of adjacent blanks and parts.

**Lubricants.** Any lubricants used with organic-coated steels must be compatible with the coating composition and must be removable in a cleaning system that is also compatible with the coating. Plastic sheets or adhesive-backed paper are sometimes used instead of, or in conjunction with, more conventional lubricants to avoid problems with compatibility or lubricant removal.

**Formability.** The wide variety of organic coatings available prevents any detailed discussion of the formability of each separate class of organic material used to coat coated sheet steels. Some organic coatings are flexible enough to withstand any forming operations that will not cause fracture in the steel substrate. The formability of other coatings is much more limited, depending on the particular coating, application method, and the appearance and protection requirements of the specific application. Coating thickness, metal pretreatment, and coating

curing parameters all strongly affect the properties and adherence of the organic coating and, subsequently, the formability of the coated sheet.

Table 3 lists several common types of organic coatings and gives the typically applied coating thicknesses, formability ratings, adhesion ratings, and minimum acceptable bend radii for each type. The coating thickness values presented in Table 3 represent the maximum and minimum thickness ranges; typical coating thickness windows will be appreciably narrower. The thickness of any primer coating is not included in the coating thickness values.

Base metal surface roughness can influence the formability of organically coated steels, especially for the thinnest coatings. Lower surface roughness values (smoother surfaces) give a more uniform distribution of stresses during the forming process, reducing the peak strains experienced by the coating and generally resulting in better surface appearance. Base metal with a rougher surface finish subjects the coating over the high spots on the substrate to higher forming stresses and greater wear during forming. This generally results in more cosmetic damage to the surface, but the lower heat generated by the reduced friction can partially or totally reduce this effect in certain applications.

**Adhesion and Flexibility.** The adhesion of commonly used coatings is rated in Table 3. The minimum bend radii and formability ratings shown are a measure of the combined effect of coating adhesion and flexibility. Vinyl plastisol

coatings have such outstanding flexibility that they can bridge cracks produced in the metal base by severe forming.

To provide the adhesion generally required for forming, chemical conversion coatings, selected for the metal surface to be painted or plastic coated, are applied to coil stock or blanks by spray or immersion treatment. This treatment is usually followed by the application of a prime coat compatible with the final coating material. Bare steel is given an iron phosphate coating with a weight of 375 to 480 mg/m<sup>2</sup> (0.013 to 0.016 oz/ft<sup>2</sup>). Zinc-coated steel receives a zinc phosphate coating—1.6 to 2.7 g/m<sup>2</sup> (0.005 to 0.009 oz/ft<sup>2</sup>) on hot dip coatings and 1.08 to 1.9 g/m<sup>2</sup> (0.0035 to 0.006 oz/ft<sup>2</sup>) on electroplated coatings. Aluminum-coated steel is treated with a chromate coating weighing 215 to 270 mg/m<sup>2</sup> (0.0007 to 0.0008 oz/ft<sup>2</sup>). These coating weights refer to area of stock and must be doubled when treatment of both sides of the stock is considered.

Organic coatings that are applied to untreated and unprimed metal surfaces have better flexibility than those applied to pretreated surfaces. However, without pretreatment or the use of a suitable primer, the degree of adhesion necessary to withstand forming forces or to have adequate service life and corrosion resistance usually cannot be assured. As indicated in Table 3, forming characteristics are generally improved by the use of a primer. An exception is tin-coated steel.

The thicker films of organosols, plastisols, and vinyl-film laminates have better flexibility than

films of solution coatings in the 0.025 mm (1 mil) dry-film range. The stress of forming is absorbed within the thicker films and is not transferred to the interface with the metal, at which adhesion is established.

Solution coatings, because of increasing film strength, have less flexibility and adhesion near the upper thickness limit. The most severe forming can be done near the lower thickness limit, but such thin coatings may not fulfill service requirements. Although solution coatings of silicone-polyesters and thermosetting acrylics can be applied as thin as 2.5 µm (0.1 mil), as exterior coatings, they are used almost exclusively in the heavier thicknesses shown in Table 3. Laminated plastic coatings may show excessive film strength and therefore less flexibility and adhesion at the upper end of the thickness range, and low tensile strength at the lower end. The color and gloss of an organic coating also affect coating flexibility, which decreases with increased pigment loading.

The hardness of organic coatings is in the range of HB to 3H pencil hardness for most of the commonly used paints and approximately Durometer A 85 to 90 for plastisol coatings and laminated plastics. Softer coatings are more likely to be damaged by scoring in the forming die. Die pressure transmitted through an organic coating to the interface can destroy adhesion. In heavy films and vinyl-film laminates, the elastic, compressible finish coating normally yields under die pressure, but the relatively brittle adhesive primer layer can be damaged by localized high die pressure.

**Shearing, Blanking, and Piercing.** Sharpness of cutting tools and direction and speed of cut affect the performance of coatings in the cut area. Dull cutting tools or high impact speeds cause high-energy impact on the coating surface and may shatter the bond in the surrounding areas, particularly in coatings of borderline adhesion strength. Flaking or lifting of the coating may result.

**Bending.** Minimum bend radii for organic-coated metals are given in Table 3. Slow bending will prevent breakage of the coating more effectively than rapid bending. When bending with contour forming rolls, the finish of the organic coating will be preserved, and less stress will be imposed on the steel base if the radii are bent over several rolls instead of one or two rolls.

Bending short flanges close to a cut edge or where the coating is scored by the bending tool at the peak of the bend can cause the coating to lift off the steel base. In both cases, the cohesive strength of the film has been weakened, and coatings with high film strength will attempt to return to the shape in which they were applied.

**Deep Drawing.** Suitability of the organic-coated metals for deep drawing (or severe forming) is also rated in Table 3. The effect of speed of drawing or forming is generally the same as that described for bending. The more

**Table 3 Forming characteristics of organic precoated sheet steels**

For coiled bare, hot dip or electrogalvanized, and aluminized steels. Applied also to aluminum, copper, and brass substrates. For tin-coated steel, ratings apply only for epoxy coatings; other coatings have lower ratings. For copper and brass, ratings apply only when primers based on epoxy or phenolic resins are used. Data are based on the use of suitable chemical conversion treatments and primers; results may vary for different substrates. Conversion coatings and primers improve results with most coating-substrate combinations.

(a) Ratings: E, excellent; G, good; F, fair. (b) *t*, thickness of sheet. (c) Results are greatly affected by coating thickness. (d) Coating of medium thickness is good for deep drawing. (e) Coating can bridge cracks in the metal produced by severe forming; compressibility of the coating must be considered in forming to close tolerances. (f) Results are greatly affected by substrate material and thickness. (g) Bonds may be destroyed in extreme draws or sharp bends. (h) Bond strength may be seriously reduced after slight deformation. (i) Particularly susceptible to damage by scoring of coating during forming

steps used, the more severely a part can be drawn or formed without damaging the organic coating. However, the ductility and work-hardening behavior of the steel, as well as the flexibility of the coating system, must be considered in the design of a forming or drawing die.

**Forming Temperature.** Depending on the effect of temperature on the properties of the organic coating, heating up to 50 °C (120 °F) before forming will reduce the likelihood of coating fracture. Some coatings, such as silicone-polyester coatings with a high silicone content, can be formed at a temperature as high as 65 °C (150 °F). Heating can be done with infrared radiant heaters, hot air, or an open gas flame or by storing the coil stock in a heated room until fabrication. Overheating must be avoided. Organic coatings, especially the thermosetting types, can be softened enough to make them subject to surface damage from die action and handling.

The design and surface finish of tools and the selection of handling procedures and equipment are important in forming organic-coated metals. Depending on the accuracy requirements and the coating thickness, allowance may have to be made for the coating thickness in dimensioning the forming tools. When accuracy requirements and coating thicknesses permit, the same dies can often be used for painted and plated metals.

To prevent scratching and scoring of pre-painted surfaces, the die surfaces must be polished and sharp corners rounded off. In

addition, damage during ejection and subsequent handling of the parts must be prevented.

# Forming of Steel Strip in Multiple-Slide Machines

**MULTIPLE-SLIDE FORMING** is a process in which the workpiece is progressively formed in a combination of units that can be used in various ways for the automated fabrication of a large variety of simple and intricately shaped parts from coil stock or wire. Operations such as straightening, feeding, trimming, blanking, embossing, coining, lettering, forming to shape, and ejecting can be done in one cycle of a multiple-slide machine. Forming is generally limited to bending operations, but the four slides and center post permit the fabrication of very complex parts, as described in more detail in the article "Multiple-Slide Machines and Tooling" in this Volume. Deep drawing is generally not done in the forming or press stations of a multiple-slide machine.

## Applicability

Multiple-slide forming is used to produce shapes from coiled strip or wire. The maximum size of workpiece that can be formed from strip metal in a multiple-slide machine is 203 mm (8 in.) wide by 685 mm (27 in.) long. Parts made from wire up to 1015 mm (40 in.) long (or longer if a special machine is used) and up to 9.5 mm ( $\frac{3}{8}$  in.) in diameter can be formed automatically from coil stock. This article deals with the forming of strip stock; the fabrication of wire forms is discussed in the article "Forming of Wire" in this Volume.

If the work metal is comparatively thin and the bending is not severe, tempered strip material can be formed. Plated or coated materials can be formed, but it is usually better to coat after forming because it is difficult to avoid marring coated surfaces during forming. However, non-metallic inserts at appropriate points in the straightener, feeder, and forming tools can be used to reduce tool marks.

Springback must be considered in bending such materials as stainless steel, phosphor bronze, certain grades of brass and beryllium copper, or high-carbon steel. Adjustments can be made in the forming tools to provide the amount of overbending required for the accuracy of the finished work.

More than one piece can be made in each cycle of a multiple-slide machine. For example, a part that had been made in seven conventional press operations was replanned for the multiple-slide production of four pieces per cycle at 200 cycles per minute.

## Multiple-Slide Machines

Multiple-slide machines are made in a range of sizes, all similar in construction and principle. The larger machines have a longer die space, which enables more die stations to be used for the manufacture of complicated components. Generally, the number of strokes per minute decreases and the horsepower increases as the machine size increases.

The four forming slides of a typical multiple-slide machine are generally sufficient for ordinary part-forming needs. However, complex parts can be formed at two or three levels around the center post, thus doubling or tripling the number of forming positions available.

Figure 1 shows a plan view of the main units of a medium-size multiple-slide machine that uses a floor space of 3.7 by 1.5 m (12 by 5 ft), including the stock reel. Four shafts (A, B, C, and D), mounted to a flat-top bedplate, are driven at equal speed through spur gearing (E) by an electric motor. Each of the four shafts is fitted with a positive-action cam (F) that drives a slide (G) (only two of four are identified) on which the forming tools can be secured. In the center of the machine is a vertical post (H) into which the center post or former is fixed and around which the work material is bent. The formed workpiece is removed from the center post by a stripper mechanism, which usually consists of a hardened steel plate surrounding the center post and secured to a vertical rod operated by a cam (F) on the right-hand shaft to give up-and-down motion to the stripper. All of these parts constitute the forming station of the machine.

To the left of the machine proper is a stock straightener (L), shown in working position with strip stock passing through it. Intermittent feeding of the work metal is accomplished by an automatic gripper in the feed slide (M) and an adjustable crank (O), which is attached to a

shaft (C). A separate gripper (P) is provided with cam-operated jaws, which grip the strip on the return stroke of the feed slide to prevent backward motion of the strip.

The work metal strip, fed through the machine in a vertical plane (on edge), passes horizontally through dies in a horizontal press (Q). A short, powerful stroke is given to the horizontal press slide by a cam on the front shaft (D) (Fig. 2).

**Stock straighteners** used on multiple-slide machines are similar to those on stamping presses. The primary difference is that in a multiple-slide machine the rolls are mounted vertically to straighten the work metal as it passes through the machine on edge, instead of horizontally as in a conventional press (see the article "Multiple-Slide Machines and Tooling" in this Volume).

**The stock-feed mechanism** of a multiple-slide machine is made of two separate units constituting the forward gripping and transporting device (Fig. 1, M) and a stationary gripping unit (P) to hold the strip when it is released on the return stroke of the feed. The stock-feed slide is reciprocated through a system of links from a crank disk keyed to the left-hand camshaft of the machine (Fig. 1, M, O, and C).

**Press Station.** The die used for piercing, trimming, embossing, and minor forming of the stock is mounted in the press station, which consists essentially of a horizontal press operated by a cam on the front shaft (Fig. 1, Q and D). It may consist of a single unit, as shown in Fig. 2, or additional units can be placed side by side, especially in the larger machines.

Die head units can also be operated from front, rear, or both in machines that are constructed symmetrically. Burr direction can be controlled at designer option.

Cams provide a positive movement to the press slide in both directions so that the tools are withdrawn from the strip at the end of the working stroke. A dwell at completion of the in-stroke provides time for opposing motions. This permits working cleanly from each side of the stock. A means of adjusting the shut height of the die is provided. The entire unit can also be moved longitudinally along the bedplate to the desired position established by the feed length. A bolster provides support for the die shoe, and a

cam-actuated ram provides support and motion for the punch holder.

**The cutoff unit**, placed between the press and the front forming slide, is used for cutting work metal into blanks before they are bent to shape. The ends can be cut off straight, or the cut can be curved.

Various types of cutoff units are described in the article "Multiple-Slide Machines and Tooling" in this Volume. The cutoff unit consists

basically of a horizontal slide that is operated through a lever from a cam on the front shaft. The unit can be adjusted along the bedplate in order to cut off the blank at the required distance from the center post. A positive cam action returns the slide so that the cutoff tool will not interfere with forming. Generally, the cutting die and stripper, through which the work metal is fed, are stationary, while the punch moves to cut off the blank.

It is sometimes desirable to install a second cutoff unit on the right-hand side of the center post. The two units trim the two ends of the blank to an accurate length. Because both ends of the blank are trimmed, slightly more stock is required when this method is used, but the inaccuracies of a long feed length are corrected.

**The forming station** consists of four slides, a center post, and a stripper mechanism. Shaped tools in the four slides progressively bend the workpiece around the center post. In most applications, the center post controls the shape of the workpiece. The first forming tool, usually on the front slide, holds the blank against the center post during cutoff.

Each of the four forming slides runs in its own slideway machined in the bedplate, and each slide is operated positively in both directions by cams. The front, rear, and right-hand slides are all similar in design; the left-hand slide is different because it must pass underneath the press unit.

The tool holder and slide have a mating key and keyway machined parallel to the slide motion so that the forming tool can be adjusted in this direction. A keyway in the top of the tool holder at right angles to the slide movement and a mating key on the end of the forming tool allow sidewise adjustment. The cam that operates each forming slide is made in two halves and has radially disposed slots so that it can be easily exchanged or timing can be adjusted.

The unit shown in Fig. 3 holds the center post rigidly in position for the forming tools to operate around and provides the means for stripping the completed parts off the center post. The center post is fitted and rigidly secured to a king post, which generally consists of a square or rectangular steel bar. The king post fits into a recess in an overhead horizontal slide and is clamped in position by a steel plate and screws. This arrangement holds the king post and center tool rigid and allows for easy adjustment of the vertical position of the center post. The center tool is held square with the forming tools at all times.

The overhead slide, carrying the center post, moves parallel with the front and rear slides and is pushed backward by the action of the front tool holding the strip against the center post until the slide reaches a stop, when the metal is bent to shape. When the front tool retracts, the slide containing the center post is returned by spring pressure until a stop is reached. If desired, the slide can be held in a fixed position by adjustment of the two stops. The sliding center post arrangement minimizes interference between the cutoff die and the left-hand slide tools.

Workpieces are ejected from the center post by the downward movement of a suitably shaped stripper plate. The stripper plate is held on a vertical rod, which derives its motion through a system of levers from a positive-action cam on the rear shaft. During forming, the stripper plate is positioned above the forming tools. The vertical rod is guided by a bushing in the overhead slide.

**Fig. 3** Unit containing cam-operated stripping mechanism and horizontal slide for mounting of the center post assembly. See text for details.

The stripper-cam lever has provision for the roller to be in one of two positions. With the roller as shown in position Fig. 3, A, the cam acts as a normal ejector, moving quickly down and returning the stripper rod almost immediately. With the roller in position B, the rod is held down for a longer period and remains in the upward position only for a short time. This arrangement is used when a retractable mandrel is attached to the mechanism in place of a stripper plate. The mandrel can be held down for a long time while the forming takes place and can then be quickly retracted, as may be required in a further forming or closing operation.

## Blanking

The blank that is bent to shape in the forming station has all of the prior operations done in the press station. Trimming the blank outline; piercing holes; embossing ribs, weld projections, and hole flanges; and stamping letters and numerals are done before the blank is cut off and formed. The blank is severed from the strip by cutting off, parting, or blanking methods.

**Dies** used in multiple-slide machines are either single-stage or progressive, depending on the complexity of the part being formed. Generally, a progressive die is used, even though it may be only a simple two-station pierce-and-pilot die.

The dies for producing the blank must be made as accurately for a multiple-slide machine as they are for a conventional press. However, the multiple-slide dies are of a simpler design and are less expensive than conventional press dies because most of the forming is done in a separate station and around the center post.

The strip layout and die construction are similar to those for progressive dies used in conventional presses. However, as noted previously in this article, the bending operations are usually done in the forming station and cutting off is usually done in the cutoff unit, unless a transfer unit is used to transport the blank from the press station to the forming station. Air jets are used where possible to eject the pierced slugs from the die.

The forming of lanced detents and flanged holes toward the punch side of the blank can be done by actuating the punches with cams on the rear camshaft. Additional movements of

die units can be obtained from any of the three other camshafts.

**Extended dies** are progressive dies that are mounted in the press station and extend into the forming station. After the usual piercing, notching, and piloting operations, bending or forming is done by a combination of elements in the progressive die and those actuated by the front and rear camshafts. The stripper mechanism can be used to advance and retract a mandrel around which the part is bent. The moving or positioning of punches and dies by the camshafts can make it possible to use tools that are much simpler in design than those made for operations in conventional presses. The parts made in extended dies are generally those that can be retained on the strip until all operations are complete before the part is cut off.

**Cutting off** the blank is usually done with a blade and die mounted in the cutoff unit. The die is fixed to the housing across which the strip of work metal passes. The blade is secured to the slide so that when it is given a forward movement, the blank is sheared from the strip.

Basically, the cutoff tool consists of two flat pieces of metal: the cutoff die (A) and the blade (B), as shown in Fig. 4(a). A fixed stripper (D) holds the work metal (C) against the die, and when the blade moves across the face of the die, the metal is severed. Most of the parts illustrated in this article were cut from the strip by this method.

The die and blade can be modified to give a shaped cut, as shown in Fig. 4(b) to (d). The shapes illustrated can be used when forming ringlike parts that have a smooth-fitting joint.

**Shaped ends** on a workpiece can be formed by two methods. The first method consists of cutting the full contour of the ends of two adjacent parts in one machine stroke (Fig. 5a). The second method consists of partly developing the contour in the press station and then using the cutoff station to complete the contour by parting the blank from the strip by shearing the connecting tab, as shown in Fig. 5(b).

Blending of the parting punch with the previously cut contour may necessitate the use of a punch with sharp corners, which could shorten punch life. If not properly blended, flats or other evidence of mismatch will appear on the severed workpiece.

As shown in Fig. 5, the parting punch is mounted on the plate at the rear of the strip.

**Fig. 4** Four arrangements of cutoff blades and dies for multiple-slide forming machines. See text for details.

The die is fitted with a stripper into which the metal is guided across the front of the die. The die and the stripper are both mounted on the slide of the cutoff unit and move horizontally toward the punch, carrying the strip metal with them. When the work metal contacts the punch, the ends are sheared. The scrap is ejected through the die.

Normal press practice is for the die to remain stationary and the punch to move. This practice is reversed when parting in the cutoff unit so that the end of the metal can swing clear, which would not be possible if the die were at the back of the strip.

Another way in which shaped ends can be produced is to provide a cutoff unit at each side of the front forming tool, each unit being fitted with a die to cut one end. When pilots cannot be used in the die or when a long blank is being cut, the second unit helps in solving tooling problems.

**Short Blanks.** When the length of the blank is short and the end is very close to the forming slides, the cutoff blade can be fastened to the

front tool. The blade is fitted and secured to the front tool; an adjustment screw provides for positioning of the blade. The cutoff die is positioned to mate with the blade.

**Transfer of blanks** from the cutoff unit to the forming station is generally unnecessary because the blank can be moved into the forming station before it is cut from the strip. However, it is sometimes desirable to cut the blank from the strip at the last station in the progressive die, as in ordinary press blanking. In such a cycle, a transfer unit such as that shown in Fig. 6(a) is used, which transfers the blank to the forming station. The transfer head is actuated by a stub shaft located below the left-hand camshaft (Fig. 1, C).

After the blanking punch has retracted, the blank is held in the die cavity. The blank is then pushed out of the die cavity with a plunger that is moved forward by a cam fixed to the rear shaft and into the waiting pickup finger. The blank is transported horizontally to the forming station, where the first forming tool pushes the blank out of the pickup finger and against the center post.

While the forming tools are bending the blank around the center post, the transfer head moves back to the press station for another blank.

A blank can be picked up in the blanking station in one position and indexed to the forming position during the transfer motion (Fig. 6b). This permits the strip layout to be designed for optimal stock use. Bends can also be positioned favorably with respect to the rolling direction. The transfer of blanks from the blanking position to the forming position without reorientation is shown in Fig. 6(c). The pickup finger is mounted in the transfer head so that no swiveling or indexing takes place.

Timing of the transfer-head motion is important. The finger must be in position for loading or unloading but must not interfere with the blanking punch or the forming slides.

## Forming

As the work metal strip leaves the press station, it passes through the cutoff unit and between the center post and the first forming tool (usually the front tool). Simultaneously with the cutting off of the blank, the front forming tool moves forward and holds the blank firmly against the center post. By continued movement of the front tool, the blank is bent around the center post. Tools on the two side slides move in to make further bends, and these can be followed by a fourth tool on the rear slide to complete the forming. The sequence in which the slides move is not fixed, nor is it always necessary to use all four slides when forming a part.

**Holding blanks** firmly in position against the center post is necessary while they are being severed from the stock and also during the initial forming operation in order to prevent slipping and to ensure against premature bending or kinking across a weak section. The work metal is likely to bulge when a U-shaped part is being

**Fig. 5** Two types of parting dies used to shape the ends of blanks before forming. (a) Die for cutting the contour in one stroke. (b) Die for completing the contour by parting a partially developed blank from the strip

**Fig. 6** Mechanism for indexing and fixed transfer of blanks from the press station to the forming station of a multiple-slide machine

formed. Such a bulge is not removed when the tools are fully closed because the surplus metal cannot flow while the blank is held firmly by the two corners of the bending tool. In some applications, a spring-loaded plunger in the first forming tool is positioned slightly in advance of the bending portions and prevents the blank from bulging when the bends are started. A positive blankholder is essential for holding forms having a weak section between the bends or for preventing slipping or dragging of a blank around the corner when bending takes place. A partly formed blank also must be held while being moved to the lower level and until a form tool can grip it.

There are two general types of mechanically operated blankholders. One type makes use of the standard stripping mechanism, and the other is operated by a cam and lever from one of the shafts.

**Part Ejection.** After all tools are retracted, the formed part is ready for ejection by the stripper plate. During forming, the stripper plate is positioned at the top and clear of the forming tools. After forming, the stripper plate moves down and ejects the part from the center post. The stripper can also move a partly formed component into a second, or even a third, forming level on the center post.

**Multiple-Part Forming.** Forming of more than one part per cycle of the machine should be considered when planning the tools for production, but the increased loading must be within the capacity of the equipment. The way in which the

outline of the part is developed depends largely on its finished shape. If a part can be made of strip stock by piercing, cutting off, and forming, then more than one part can be made in each cycle by slitting the strip into two or more ribbons. For parts having shaped ends (for example, semi-circular), the strip can be slotted and the blank then cut off. Slotting the strip may eliminate the need for sharp corners on the punch and die, thus increasing their service lives. Parts with more complex outlines require more complex trimming punches. The blank is severed from the strip by either cutoff or parting methods.

Some parts, such as those having the basic shape of an L, are easier to form into a U-shape and then part after forming. The bottom forming level of a multiple-slide machine can be used for parting. The parting punch is positioned on the rear tool slide, and the die on the front tool. The center post has a clearance hole for the punch.

**Forming Level.** Forming can be done around the center post at the same level at which the blank enters the forming station (single-level forming) or at one or two positions below that level (two- or three-level forming). Parts can be finish formed at the lower level, resistance welded into ringlike parts, or finish formed and then cut into two or more pieces. The partly completed workpieces are usually moved to the lower level by the stripper mechanism.

Single-level forming is used when all of the bends can be made with one set of forming tools, usually with one forward stroke per machine cycle. Sometimes, a bend can be made by partly

forming, retracting the tool, doing some work by another tool, and then advancing the first tool to finish the bend. Auxiliary forming tools actuated by separate cams or lever arrangements can be used to do more work on a piece. Wide blanks are usually formed at one level because of the length of center post needed to support more than one part and because of the limited space available for mounting tools.

During two-level forming, two components are on the center post—one at the top level and the other at the bottom level. Work is done simultaneously on each piece by the forming tools. Forming is often done at both levels simultaneously by providing each slide with a tool that is shaped to perform an operation on each piece. The workpiece at the lower level is pushed off of the center post by the downward movement of the partly completed piece from the top level.

One of the simplest applications of two-level forming is the manufacture of bushings and ferrules by forming the center and the ends of the blank at the top level and finish forming to final diameter at the bottom level. A more complicated application of two-level forming is described in the following example.

**Example 1: Two-Level Forming of a Hose Clamp.** The hose clamp shown in Fig. 7 was made from cadmium-plated steel 9.5 mm ( $3/8$  in.) wide at two levels on the center post in a multiple-slide machine. At the press station, the three holes were pierced and a score mark or slight kink was formed between two holes to

Fig. 7 Forming tools used and sequence of operation in the forming of a low-carbon steel hose clamp. Dimensions given in inches

ensure that the two holes would coincide after the metal had been folded back on itself. Pilots in the press station ensured accurate location of the strip for cutoff and forming. The forming tools used for the two levels are shown at left in Fig. 7.

At position A in Fig. 7, the cutoff blade (3) sheared the blank from the strip while it was held against the center post (1) by the pressure finger (2). The front tool (4) formed the blank as shown. The side tools (5 and 6) are shown pressing the stock around the center post in position B. With the front and side tools retracted in position C, the pressure finger held the formed part against the center post while the stripper (7) moved the part to the lower level, where the spring-loaded lever arm and pressure finger (8) held the part.

In position D at the bottom level, the pivoting rear tool (9) formed the part around the center post (circular in shape at this level). The rear tool also set the folded-over metal against an extension of the front tool (4). The final forming operation by the right tool (10) was as shown in position E.

In the next cycle, the stripper pushed a new workpiece down to the bottom level, as the completed hose clamp was pushed off of the center post. The cycle time was about 60 components per minute.

**Lockseaming.** Metal strip is used to make large quantities and varieties of small open-end boxes, tubes, and cylinders to be used as ferrules for paint brushes, radio shields, and many other common products. All of these are made with some locking method for joining the ends of the metal.

In lockseaming or can seaming, one end of the metal is formed over the other and flattened into a tight joint. Other methods of locking two ends of metal together in a multiple-slide machine include interlocking dovetails, raised tabs inserted through slots and then flattened or twisted, a tongue inserted into a lanced slot and then swaged, and lancing and forming through two stock thicknesses.

Lockseaming can be done at either one or two levels around the center post. Single-level forming is used where the tubes are long or where projecting lugs would be too weak to push the finished part off of the center post. In this method, the rear and side tools must be advanced two or three times during each cycle of the machine.

Two-level forming with an attachment that gives a positive movement to the seaming tools is a more efficient method of making lockseams. The sliding head containing the center post can be used to make several sizes of lockseam tubes by setting the rear and side tools a fixed distance from the strip line, then changing only the front tool and the center post. The following example describes a two-level forming operation for external lockseaming to make a short cylindrical tube.

**Example 2: Two-Level External Lockseaming to Produce a Round Tube.** The external lockseam of the tube shown in Fig. 8 was formed at two levels in a multiple-slide machine. At position A, the strip had been fed between the center post (1) and the pressure finger (2) and sheared by the cutoff die (3) and blade (4). At the same time, the right-hand end of the

blank had a small flange formed by the fixed tool (5) and the blade (6). Position B shows the blank formed into a U-shape by the front tool (7). Forming of the cylinder by the side tools (8 and 9) is shown in position C. The two ends extend at right angles to the surface, one end being longer than the other. The right tool (10), moved by the cam (11), supported the previously bent flange as the left tool (8) formed the longer end. At position D, the left tool (12), actuated by the cam (13), bent the long end over the shorter end.

At position E, the cams (11 and 13) retracted, allowing the side tools (10 and 12) to be pushed aside by the advancing rear tool (14), thus permitting the end of the seam to be bent. The rear tool retracted, and the cam (11) advanced to move the side tool (10) to flatten the seam against the left tool (8), as shown in position F. The part then was transferred to the lower level by the stripper (not shown).

At the bottom level, the front tool (15) and the side tools (16 and 17) held the cylinder on the center post. The front tool also backed up the center post during the final forming operations. As shown in position G, the anvil (18) supported the seam while the swinging tool (19) moved forward to bend the seam at an angle. The anvil is moved by the cam (20). Final flattening of the seam is shown in position H. As the rear tool (21) advanced, the cam projection (22) contacted the anvil, pushing it clear as the swinging tool (19) closed the seam.

Two workpieces were on the center post at this stage, and both were formed at the same time. One, formed through position F, was at the top

Fig. 8 Two-level forming of an external lockseam to produce a cylindrical part. Dimensions given in inches

level; the other was at the bottom level. Both were held tightly on the center post. The completed piece was pushed off of the center post and into a container.

**Internal lockseams** can be made by forming an external seam, as shown in Fig. 8, and then re-forming the part to make the seam flush with the outer surface. The part is moved to the lower level, where a vertical slot in the center post provides space for the seam as it is pushed inward.

## Assembly Operations

By means of auxiliary feeding attachments, one or more components can be assembled to a part being formed during the same machine cycle. Hopper feeding units can sort and orient machined or previously formed parts for feeding into the part being formed in the multiple-slide machine. These devices can be arranged to feed horizontally adjacent to any forming slide, or can be operated vertically.

**Hopper feeding** involves the automatic sorting and transfer of components placed randomly in a hopper of suitable design and shape for delivery by gravity to a track, correctly positioned and in ordered sequence to a machine.

**Production Practice.** Figure 9 shows the assembly of a flat steel spring into a small steel bracket at the lower level of a two-level multiple-slide machine operation. The bracket was made from 12.7 mm (1/2 in.) wide stock 0.76 mm (0.030 in.) thick. In the press station, the two

holes were pierced, and the lug was slit and raised. The bracket was bent to shape around the center post at the top level by the action of the front, rear, and right forming tools. It was then moved to the bottom forming level by the stripper and held in position against the center post by a spring-loaded retainer. A sliding pin mounted in the retainer was used to flatten the lug against the spring steel strip.

The spring steel strip was fed into the recess formed by the lug. The front tool then moved in, contacted the sliding pin, flattened the lug, secured the strip to the bracket, and at the same time severed the spring steel strip by a blade mounted to the front tool.

On the next cycle, the assembly was ejected from the center post by the downward movement of the succeeding component. The lower part of

the spring-loaded retainer was cut away to clear the strip as it was fed into the lug and to permit ejection.

### Multiple-Slide Rotary Forming Machines

The multiple-slide rotary forming machine with open planetary gearing is simple in concept and design. In this type of machine, the slides are driven by a central gear wheel, and the central forming motions are controlled by cams.

Figure 10 shows a schematic of a multiple-slide rotary forming machine. The material is first uncoiled from the reel, then pulled through the straightening station (A) by the material feeder (B). It is then fed to the press (C) and

forming slides (D), where the workpieces are formed and ejected. Recessed rails guide the material between the feeder and the stamping station, as well as between the cutting and forming stations. Here, the blanks are either completely stamped out in the press and then pushed into the bending station by the following material, or they remain attached to the strip by means of a web that is not completely separated until it reaches the final forming station. Material feed, stamping presses, forming slides, and operation of the central tool are synchronously coupled to each other.

**Auxiliary Equipment.** A second material feed and press, a part-feeding mechanism, three thread-tapping units, and two welding units can be added to a multiple-slide rotary forming machine (Fig. 10). It is possible to have

additional material feeds from the front and rear sides. Additional cam motions allow forming slides and standardized tools to be mounted on the rear side of the bed in the forming area. Machined assembly surfaces on the bed and cover plate offer further possibilities for fastening attachments.

**Standardized Tooling.** The forming tool guide (the basic tool) consists of the tool plate with a central slider for one or more tools (Fig. 11). Forming tools are suspended in the tool holders mounted on the forming slides, which can be easily inserted or removed. In operation, the tool guide is enclosed by a cover plate, with an opening at its center for ejection of the working piece. Control cams drive the forming slides and consist of two complementary disk cams.

# Forming of Stainless Steel

Revised by Joseph A. Douthett, AK Steel Corporation, Inc.

STAINLESS STEELS are blanked, pierced, formed, and drawn in basically the same press tools and machines as those used for other metals. However, because stainless steels have higher strength and are more prone to galling than low-carbon steels and because they have a surface finish that often must be preserved, the techniques used in the fabrication of sheet metal parts from stainless steels are more exacting than those used for low-carbon steels. In general, stainless steels have the following characteristics, as compared with those of carbon steels:

- Greater strength
- Greater susceptibility to work hardening
- Higher propensity to weld or gall to tooling
- Lower heat conductivity

## Selection of Alloy

General ratings of the relative suitability of the commonly used austenitic, martensitic, and ferritic types of stainless steels to various methods of forming are given in Table 1. These ratings are based on formability and on the power required for forming.

As Table 1 shows, the austenitic and ferritic steels are, almost without exception, well suited to all of the forming methods listed. Of the martensitic steels, only types 403, 410, and 414 (the lower-chromium and -carbon alloys) are generally recommended for cold forming applications. The higher carbon content of the remaining martensitic alloys and higher hardness of the martensitic precipitation-hardenable alloys 17-4PH or 15-5PH act to limit the formability of these alloys. Moderate warming can be used to improve the formability of these alloys, as in general with all the classes of stainless steels. Most martensitic stainless alloys are mill supplied with an in-process anneal generally between 650 and 760 °C (1200 and 1400 °F). This subcritical temperature cycle is designed to transform the martensite present into chromium carbides and ferrite. Hardness is reduced to 80 to 90 HRB, thereby improving formability. With carbides present, the alloy resistance to corrosion is reduced. After forming, a resolution-hardening heat treatment is required to return the alloys to maximum corrosion resistance.

The forming of higher-carbon martensitic alloys is normally restricted to blanking, piercing, and mild bending. These steels are sometimes formed warm. Warm forming can also be used to advantage with other stainless steels in difficult applications.

**Formability.** The characteristics of stainless steel that affect its formability include yield strength, tensile strength, ductility (and the effect of work hardening on these properties), and the

*r*-value. The composition of stainless steel is also an important factor in formability. Figure 1 compares the effect of cold work on the tensile strength and yield strength of type 301 (an austenitic alloy), types 409 and 430 (both ferritic alloys), and 1008 low-carbon steel sheet.

In Fig. 1, it is noteworthy that the three stainless alloys all have higher tensile strengths than 1008 carbon steel after any given amount of cold reduction. One reason for this finding is that

**Table 1 Relative suitability of stainless steels for various methods of forming**

Suitability ratings are based on comparison of the steels within any one class; therefore, it should not be inferred that a ferritic steel with an A rating is more formable than an austenitic steel with a C rating for a particular method. A, excellent; B, good; C, fair; D, not generally recommended

(a) Severe sharp bends should be avoided.

the initial annealed tensile strength of the stainless alloys is greater than that of 1008. The rate of work hardening (how fast strength levels increase with strain or cold work) is measured by determining the  $n$ -value. The  $n$ -value is the slope of the true stress-strain curve determined by the uniaxial tension test. The measurement is made between predetermined strain levels usually 10% to the ultimate. Steel values normally range from 0.15 to 0.50, with annealed carbon steels, ferritic stainless, and martensitic alloys at 0.15 to 0.25, and austenitic stainless at 0.35 to 0.6. The higher work-hardening rate of 300-series austenitics, as can be seen in Fig. 1, is a key factor in needing better lubricants when drawing stainless alloys, particularly when forming is carried out in multiple stages.

**Formability of Austenitic Types.** Type 301 stainless steel has the lowest nickel and chromium contents of the standard austenitic types. It also has the highest tensile strength in the annealed condition. Among the 200-series Cr-Mn-Ni-N austenitic alloys, type 201 would be considered an alloy equivalent to type 301, although the typical yield strength of type 201 is higher and tensile strength lower. The extremely high rate of work hardening of type 301 results in appreciable increases in tensile strength and yield strength with each increase in the amount of cold working, as measured by cold reduction (Fig. 1). The  $n$ -value for this alloy can typically

be measured at 0.45 or higher. This response to work hardening is particularly important for structural parts, including angles and channel sections, that, after fabrication, are expected to have additional strength and stiffness. On the other hand, for deep-drawing applications, a lower rate of work hardening is usually preferable ( $n$ -values of 0.38 to 0.42) and can be obtained in the austenitic alloys that have higher nickel contents, notably, types 304, 304L, and 305.

In general, the austenitic alloys are more difficult to form as the nickel content or both the nickel and the chromium contents are lowered, as in type 301. Such alloys show increased work-hardening rates (higher  $n$ -values) and are less suitable for deep-drawing or multiple forming operations. The presence of the stabilizing elements niobium, titanium, and vanadium, as well as higher carbon contents, also exerts an adverse effect on the forming characteristics of the austenitic stainless steels. Therefore, the forming properties of types 321 and 347 stainless steel are less favorable than those of types 304 and 305.

In general, an austenitic alloy work-hardening rate ( $n$ -value) decreases with increasing alloy content. The more solid-solution (chromium, nickel, manganese, copper) and interstitial (carbon, nitrogen) alloying elements added to a standard 300-series alloy, the lower the resultant work-hardening rate and the more deep drawable

the alloy. In recent years, copper additions of 0.5 to 4.0% have been added to effect such a reduction.

In large part, the higher work-hardening rate of 301 and lower-nickel 304 alloys is attributable to the formation of strain-induced or deformation martensite, a magnetic body-centered tetragonal crystalline phase, in the austenitic grain structure. While this phase has the same composition as the face-centered cubic austenite from which it transformed, it is stronger, harder, and somewhat needlelike in microstructural appearance. The volume of this phase that forms during cold work is dependent on the alloy composition, amount of cold deformation, and temperature of forming. The lower the alloy content (lower the nickel, chromium, manganese, copper, carbon, nitrogen) of the austenitic alloy being formed and the greater the degree of cold work, the more volume percent deformation martensite that will form.

Temperature of forming is a third key determinant of the amount of deformation martensite that forms during cold deformation of an austenitic alloy. The lower the temperature, the greater and more rapid the transformation. Conversely, heating a leaner alloyed 300-series stainless steel reduces the transformation rate of austenite to martensite. For each alloy composition, a critical temperature called the martensite deformation (MD) temperature exists where warming above this temperature suppresses the shear transformation to martensite. Cooling below this MD temperature will conversely induce the transformation, with the lower the temperature, the greater the degree of formed martensite. Figure 2 visualizes the deformation martensite tendencies discussed previously. While dependent on alloy content, the MD temperature will vary from well below room temperature for high-nickel austenitic stainless steels such as 305, 309, and 316 to somewhere between room temperature up to perhaps 93 °C (200 °F) for leaner 304 versions or 301/201 stainless alloys. When forming metastable austenitic alloys (leaner alloys that more readily form deformation martensite), adiabatic heating due to deformation can raise the part temperature above the MD temperature and slow down the strengthening or work-hardening effect due to

**Fig. 1** Comparison of work-hardening qualities of type 301 austenitic stainless steel, types 409 and 430 ferritic stainless steels, and 1008 low-carbon steel

**Fig. 2** Comparison of deformation martensite formation tendencies versus temperature, amount of cold work, and alloy content. Type 301 is a lower-alloy 17%Cr-7%Ni 300-series austenitic alloy versus a more highly alloyed 18%Cr-8%Ni type 304 alloy.

the formation of martensite. In multiple forming operations, such as progressive die setups, interrupting the stamping cycle of a 301 or 304 part can mean that with press restart, partially formed pieces will stamp differently. The cooler part will form a greater volume of martensite than one kept warm without a forming cycle interruption.

**Formability of Ferritic Types.** The range between yield strength and tensile strength of types 409 and 430 narrows markedly as cold work increases, as shown in Fig. 1. This response is typical of the ferritic alloys and limits their formability (ductility) (in comparison with the austenitic alloys). Nevertheless, types 409 and 430, although lacking the formability of type 304, are widely used in applications that require forming by blanking, bending, drawing, or spinning. One of the most important applications for type 430 stainless steel is in automotive trim or molding. Type 409 stainless steel has found wide acceptance as the material of choice in automotive exhaust systems.

The ferritic stainless alloys, in many respects, act like stronger, somewhat less ductile low-carbon steels. Their work-hardening rate ( $n$ -value) is similar to or slightly less than 1004/1008 carbon steel. The plastic strain ratio ( $r$ -value) for 409 or 430 stainless at 1.1 to 1.8 is somewhat less than the 1.5 to 2 value typical of drawable low-carbon cold-rolled steels.

In addition, the ferritic stainless alloys can present some unusual forming problems in the cold work forming of thicker sections. At cooler temperatures and higher strain rates, ferritic stainless steels can fail in a brittle manner due to a lack of toughness. Toughness is defined as the ability of a material to absorb a large volume of impact energy and deform in a ductile manner. Carbon steels and ferritic stainless alloys have a characteristic temperature or range of temperatures above which alloy specimens absorb a large volume of energy and fail in a ductile manner when impact loaded and below which impact loads cause brittle fracturing at low levels of absorbed energy. This alloy characteristic temperature is known as the ductile-to-brittle transition temperature (DBTT). Figure 3 shows plots of absorbed impact energy versus test temperature for two alloys subjected to impact testing.

**Fig. 3** Ductile-to-brittle transition temperature (DBTT) curves for two ferritic alloys. Alloy 1 has a well-defined transition temperature. Alloy 2 has a higher and less well-defined DBTT.

Alloy 1 shows a transition from ductile (high absorbed energy levels) to brittle behavior at a specific temperature, while alloy 2 shows the same behavior change over a range of temperatures. With materials such as alloy 2, the transition temperature is more difficult to pinpoint. Frequently, a specified amount of absorbed energy per unit area of sample cross section ( $W/A$  of 1000 ft-lb/in.<sup>2</sup> in Charpy tests) is chosen as the minimum value to exceed to be classified as ductile behavior.

With ferritic stainless steels, the DBTT depends on alloy content, thickness, grain size, the presence of cold work, and strain rate. For higher-alloyed (18% Cr and above) ferritic stainless steels, the DBTT can range from below  $-18^{\circ}\text{C}$  ( $0^{\circ}\text{F}$ ) for 1 mm (0.040 in.) thick material to above  $40^{\circ}\text{C}$  ( $100^{\circ}\text{F}$ ) for 2.5 mm (0.100 in.) and thicker. As ferritic alloy content increases, so does the DBTT for materials of the same thickness. Larger grain sizes also lead to higher DBTTs, as does the presence of a weld. The presence of embrittling second phases (sigma or carbides due to sensitization) can lower toughness. Finally, the DBTT of a well-annealed base alloy is lower than for the same material after cold working or forming. Stored strain energy reduces the amount of impact energy that can be absorbed if the partially cold-worked material is impact loaded.

In forming ferritic stainless steels, the concern for unexpected DBTT cracking, particularly in colder winter months or in northern climates, has given rise to the following precautions:

- Do not attempt to form ferritic stainless alloys when cold. Store raw material in heated areas, or intentionally warm just prior to fabrication.
- If brittle fracturing occurs, consider moderate warming ( $20$  to  $60^{\circ}\text{C}$ , or  $70$  to  $140^{\circ}\text{F}$ ).
- If warming still leads to brittle-appearing fractures, consider reducing the rate of forming.
- Take the greatest cold-weather precaution with higher-alloyed ferritic stainless alloys (superferritics, 25 to 30% Cr, more than 439 and 439 more than 409).
- Take greater precaution with thicker materials (above 2.5 mm, or 0.100 in., thick).
- Coarser-grained materials and welds should be given care.
- The presence of cold work should dictate added care.

This last precaution can come into play in forming parts in multiple stages. If the forming sequence is done in-line (transfer press) or rapid sequence (cell operation), the alloy is warmed by deformation and, in spite of being cold worked, may pass through the subsequent forming steps above the DBTT. Interrupting the sequence of forming can allow partially produced parts to cool down and lead to brittle fractures when the cycle again commences. Originally, the annealed incoming ferritic alloy had a DBTT below room temperature, but initial forming imparted cold work, boosting the DBTT to room temperature or above. Interrupting the forming sequence per-

mitted components to then cool below the transition temperature, setting the stage for fracture on restart.

**Comparison with Carbon Steel.** The curves for 1008 low-carbon steel are included in Fig. 1 as a reference for the evaluation of stainless steels. The decrease in formability of 1008 steel with cold work appears to fall between that of types 409/430 and that of the more formable type 301. Figure 1 also shows that cold work does not increase the strength of 1008 as rapidly as it does that of type 301 and the ferritic alloys.

**Stress-Strain Relations.** Figure 4 shows tensile test load-elongation curves for six types of stainless steel: four austenitic (202, 301, 302, and 304), one martensitic (410), and one ferritic (430). The figure also shows that the type of failure in cup drawing of the austenitic types was different from that of types 410 and 430. The austenitic types broke in a fairly clean line near the punch nose radius, almost as if the bottom of the drawn cup were blanked out; types 410 and 430 broke in the sidewall in sharp jagged lines.

As suggested by the data in Fig. 4, the power required to form type 301 exceeds that required by the other austenitic alloys. In addition, type 301 will develop maximum elongation before failing. Much of the additional power required to form 301 and the greater elongation of the alloy in tensile tests can be attributed to the alloy tendency to form deformation martensite ( $\alpha'$ ). The martensite that forms due to shear deformation is harder and stronger than the austenite from which it transformed. The martensite hardness, as with carbon steels, is proportional to the weight percent carbon and nitrogen present. The 201 and 301 melt compositions with higher carbon and nitrogen contents would be expected to form a higher-hardness deformation martensite, assuming the overall composition is lean enough and the temperature is at or below the earlier described MD so that martensite forms with cold work. As the 301 tensile specimen of Fig. 4 is pulled to form the load/elongation curve, specimen strain with accompanying thinning would trigger martensite formation and thereby strengthen the initially necked region. Tensile strain and necking would then be transferred to specimen regions adjacent to the transformed area. Once more, strain and necking would initiate martensite formation, strengthening, and additional transfer of the strain to an adjacent region along the tensile blank. With such a sequence of events, the 301 tensile blank develops a greater amount of overall elongation before the transformation sequences cease and the martensite-containing tensile dogbone section necks and fractures. Types 410 and 430 require considerably less power to form but fail at comparatively low elongation levels.

**Power requirements** for the forming of stainless steel, because of the high yield strength, are greater than those for low-carbon steel; generally, twice as much power is used in forming stainless steel. Because the austenitic steels work harden rapidly in cold forming operations, the need for added power after the

Fig. 4 Comparison of ductility of six stainless steels and of the types of failure resulting from deep drawing

start of initial deformation is greater than that for the ferritic steels. The ferritic steels behave much like plain carbon steels once deformation begins, although higher power is also needed to start plastic deformation.

## Lubrication

Lubrication requirements are more critical in forming stainless steels than in forming carbon and alloy steels, because it usually is necessary to preserve the high-quality surface on stainless steels and because stainless steels have higher strength, greater hardness, lower thermal conductivity, and higher coefficient of friction. In forming stainless steels, galling and spalling occur more readily, and higher temperatures are reached in a larger volume of the workpiece. Local or general overheating can change the properties of the work metal and lubricant.

Table 2 lists the lubricants ordinarily used in forming stainless steel by various processes. Except for the special-purpose lubricants graphite and molybdenum disulfide, the lubricants are listed in the approximate order of increasing ability to reduce galling and friction. The ratings in Table 2 also consider other suitability factors, such as cleanliness and ease of removal. The desirable characteristics of a lubricant include the ability to reduce friction and wear, the dissipation of heat, durability, nonreactiveness with the base steel, and ease of removal. The higher temperatures generated when forming stainless alloys, particularly the austenitic varieties, frequently lead to breakdown of the polar lubricant molecules.

In recent years, a family of organic waterborne polymer dry-film lubricants has been introduced that can be roll coated onto stainless steel coils and moderately warmed (95 °C, or 200 °F) to dry or cure in-line. These dry-film lubricants

applied in uniform film thicknesses measuring 1 to 3 g/m<sup>2</sup> have proven to have very low (0.05) coefficients of friction, resist buildup on tooling, can be welded without removal, and can be readily removed, depending on formulation, with either warm water or alkaline detergents. Dry-film lubricants are not recommended for use with other wet lubricants.

Among stainless steel lubricants for severe drawing applications, the extreme-pressure (EP) additive types are the most desirable. Additives of chlorine or sulfur tend to react chemically with the steel surface at higher temperatures and form a readily shearable compound. Chlorine is the more popular EP additive, because sulfur tends to react with some steel tooling.

Mineral oils, soap solutions, and water emulsions of general-purpose soluble oils are omitted because they are ineffective in most forming of stainless. The recommended lubricants are discussed further in the sections that deal with the individual forming processes in the remainder of this article.

As a precaution, all lubricants should be removed, and the parts thoroughly dried, after completion of the sheet metalworking operation. Most lubricants must be removed before the formed parts are heat treated; this applies particularly to those containing insoluble solids, sulfur, or chlorine. In addition, certain metastable austenitic stainless alloys can react with their lubricant and cause delayed cracking in heavily strained areas. Rapid removal of the lubricant is therefore desirable.

Chlorinated lubricants, if left on formed parts and put into service applications, could lead to pitting or stress cracking if moisture and humidity are present. Conversely, the roll coated dry-film polymer lubricants painted onto stainless coils do not seem to chemically react with the stainless surface and have been found to serve as a barrier coating, reducing corrosion potential for coils seeing moisture in transit.

## Blanking and Piercing

The shear strength of stainless steel is approximately twice that of low-carbon steel. Therefore, the available force for the blanking or piercing of stainless steel should be 50 to 100% higher than that for equivalent work on carbon steel.

Tools and power can be saved if the stock can be blanked at approximately 175 °C (350 °F). The finish will be better as well. Power requirements can also be reduced by using angular shear on the punch or the die.

**Die Materials.** Cutting edges must be of a hard, strong material. Recommended die materials, in order of suitability for increasing quantities, include O1, A2, D2, and D4 tool steels and carbide. Additional information is available in the article "Selection of Materials for Shearing, Blanking and Piercing Dies" in this Volume. The use of carbide for high-volume production in applications that do not require the impact

resistance of tool steels is illustrated in the following example.

**Example 1: Use of a Carbide Die to Form a Miniature Piece.** The cathode shown in Fig. 5 was produced in a three-stage progressive die made of carbide by piercing, blanking, and forming. The piece was trough-shaped, 6.4 mm ( $\frac{1}{4}$  in.) long, of type 304 stainless steel, 0.08 mm (0.003 in.) thick. One end was rounded, and the other was V-shaped. The difference in contour of the two ends kept the pieces from stacking. Before forming, the blank was 9.5 mm (0.374 in.) wide. The piece was pierced with 68 holes, each 0.31 mm (0.012 in.) square. In this operation, the material was displaced by a pointed punch, rather than removed by a flat-nose punch. The pieces were cut from 152 mm (6 in.) wide strip, producing 16 pieces at a stroke. The press was a 130 kN (15 tonf) mechanical press that ran at 240 strokes per minute.

**Clearance** between punch and die should be approximately the same as that for the blanking and piercing of cold-rolled low-carbon steel. Some manufacturers use less than 0.03 mm (0.001 in.) per side; others specify 5 to 10% of stock thickness per side for sheet and 10 to 15% of stock thickness for plates and bars. Studies have shown, however, that larger clearances (12.5 to 13.5%, and even up to 42%, of stock thickness) have resulted in increased die life (see the article "Piercing of Low-Carbon Steel" in this Volume).

Cutting edges should be carefully aligned, sharp, clean and free of burrs. The importance of sharpness of cutting edges cannot be over-emphasized.

**Deburring.** Generally, stainless steel does not shear clean but leaves a rough work-hardened edge that is dangerous to handle and may adversely affect subsequent operations. Flat pieces can be rolled or pressed between dies adjusted exactly to the thickness of the stock, or

the burrs can be removed by grinding, stoning, or filing.

**Lubrication.** The blanking and piercing of stainless is often done dry, but the lubricants indicated in Table 2 are sometimes used to prolong die life. Lubricants containing sulfur or chlorine are the most effective for this purpose. Emulsions are used for high-speed work.

**Dimensions.** Pierced holes should not be smaller than the thickness of the stock. Holes larger than 3.18 mm (0.125 in.) should be spaced so that the distance between centers is not less than  $1\frac{1}{2}$  times the hole diameter. Small holes should have a distance between centers of at least  $1\frac{3}{4}$  times the diameter of the holes. Holes should never be closer together than one stock thickness, nor should the edge of blanks be less than one stock thickness from the edge of the stock. For progressive-die operation, edge distances should be between  $1\frac{1}{2}$  and 2 times stock thickness.

**Nibbling.** In some applications, an irregular contour is cut out by punching a series of overlapping holes along the contour. This process is called nibbling. A variety of unusual shapes can be cut at 300 to 900 strokes per minute by a press equipped with either a round or a rectangular punch.

## Press-Brake Forming

All of the austenitic stainless steels in the soft condition can be bent  $180^\circ$  over one stock thickness but need up to 50% more power to form than that required by low-carbon steel. Springback is more severe with austenitic stainless steels than with low-carbon steel, and it must be allowed for. Work-hardened austenitic steel can be press-brake formed only to a very limited degree. If austenitic stainless steel is heated to approximately  $65^\circ\text{C}$  ( $150^\circ\text{F}$ ), it can

be formed with appreciably less power than that required when it is cold and yet can be handled easily. A temperature of  $65^\circ\text{C}$  ( $150^\circ\text{F}$ ) is normally high enough to exceed an austenitic stainless steel MD temperature and eliminate the strengthening contribution attributed to the formation of deformation martensite.

The straight-chromium grades of stainless steels vary in their response to press-brake forming. The low-carbon stainless steels containing 12 to 17% Cr bend readily but, like the austenitic steels, need more power for bending than that required for low-carbon steel. High-chromium low-carbon types, such as 446, bend better when heated to  $175$  to  $205^\circ\text{C}$  ( $350$  to  $400^\circ\text{F}$ ). The heating of these high-chromium low-carbon grades tends to lower the yield strength but can simultaneously aid in allowing the forming to be done above the brittle-to-ductile transition temperature. For these alloys, that temperature can be at or above room temperature, depending on thickness. In room-temperature forming, the highly alloyed ferritic stainless steels have been known to benefit from slower bend speeds, which minimize the possibility of an impactlike load and resultant brittle fracture. High-carbon heat-treatable stainless steels are not recommended for press-brake forming, even if in the annealed condition.

Typical bending limits for the major stainless steels are shown in Table 3. A completely flat bend can generally be made in the 18-8 and similar alloys.

**Dies.** Press brakes can use dies with cross sections such as those shown in Fig. 6 for forming stainless steel in sheets up to 0.89 mm (0.035 in.) thick. Adjustable dies, such as that shown in Fig. 7, can be used for forming  $180^\circ$  bends in stainless steel sheet 0.30 to 0.46 mm (0.012 to 0.018 in.) thick.

**Springback** is a function of the strength of the material, the radius and angle of bend, and the thickness of the stock; the thicker the stock, the less severe the problem. Table 4 shows the relationship between radius of bend and springback for three austenitic stainless steels. Ferritic steels usually exhibit less springback than austenitic steels, because the rate of work hardening of ferritic steels is lower. As a practical guide, the amount of springback is normally proportional to  $(0.2\text{YS} + \text{UTS})/2$ , where YS is yield strength, and UTS is ultimate tensile strength.

**Table 2 Suitability of various lubricants for use in the forming of stainless steel**

Ratings consider effectiveness, cleanliness, ease of removal, and other suitability factors.  
A, excellent; B, good; C, acceptable; NR, not recommended

Lubricant	Blanking and piercing	Press-brake forming	Press forming	Multiple-slide forming	Deep drawing	Spinning	Drop-hammer forming	Contour roll forming	Embossing
Fatty oils and blends(a)	C	B	C	A	C	A	C	B	B
Soap-fat pastes(b)	NR	NR	C	A	B	B	C	B	C
Wax-based pastes(b)	B	B	B	A	B	B	C	B	A
Heavy-duty emulsions(c)	B	NR	B	A	B	B	NR	A	B
Dry-film (wax, or soap plus borax)	B	B	B	NR	B	A	B	NR	A
Pigmented pastes(b)(d)	B	NR	A	B	A	C	NR	NR	NR
Sulfurized or sulfochlorinated oils(e)	A	A	B+	A	C	NR	A	B	A
Chlorinated oils or waxes(f)									
High-viscosity types(g)	A(h)	NR	A	NR	A	NR	A(j)	A	NR
Low-viscosity types(k)	B+	A	A	A	B	NR	A(j)	A	A
Graphite or molybdenum disulfide(m)	NR	(n)	(n)	NR	(n)	NR	(n)	NR	NR

(a) Vegetable or animal types; mineral oil is used for blending. (b) May be diluted with water. (c) Water emulsions of soluble oils; contain a high concentration of extreme-pressure sulfur or chlorine compounds. (d) Chalk (whiting) is commonest pigment; others sometimes used. (e) Extreme-pressure types; may contain some mineral or fatty oil. (f) Extreme-pressure chlorinated mineral oils or waxes; may contain emulsifiers for ease of removal in water-based cleaners. (g) Viscosity of 4000 to 20,000 SUS (Saybolt Universal seconds, see ASTM D 2161 for more detailed information). (h) For heavy plate. (i) For cold forming only. (k) Viscosity (200 to 1000 SUS) is influenced by base oil or wax, degree of chlorination, and additions of mineral oil. (m) Solid lubricant applied from dispersions in oil, solvent, or water. (n) For hot forming applications only

**Fig. 5** Cathode produced in a progressive die with carbide tools. Dimensions given in inches

Springback can be controlled by reducing the punch radius, by coining the line of bend (if the shape of the die is such that bottoming is feasible), and by overbending. For overbending, it is sometimes necessary only to make the punch angle smaller than the desired final angle of the workpiece, as in the following example.

**Example 2: Setting a Flange Angle in a Press Brake.** The bracket shown in Fig. 8 was preformed in a U-die from a developed blank of type 302 stainless steel, half-hard, 1.0 mm (0.040 in.)

thick. Only the punch angle needed to be reduced to set the angle on the flange.

As the bracket came from the U-die, the springback in each flange was  $15^\circ$ . To correct this spread, the piece was put in a restrike die in a press brake, which set each angle separately. The restrike die angle was  $90^\circ$  with a 3.2 mm (0.126 in.) radius. The restrike punch was made to an angle of  $86^\circ$  with a 2.4 mm (0.094 in.) radius to coin the bend, so that the flanges would form to  $90^\circ \pm 1^\circ$ .

The lubricant was a water-soluble pigmented drawing compound. The workpiece was degreased after forming.

**Lubricants.** For ordinary press-brake operations (chiefly, bending and simple forming), lubricants are not used as frequently as with

higher-speed press operations. Convenience of use is a major factor in selecting lubricants for this type of press-brake forming. Pigmented lubricants are not favored, and cooling effectiveness is of little significance at low production rates. For severe forming and for operations that would ordinarily be done in a press, if available, the recommendations in the "Press forming" column in Table 2 apply.

**Applications** of press-brake forming are described in the following examples. Repetitive bends, as in corrugated stock, are frequently made one at a time in a press brake if the quantity of production is not sufficient to warrant a special die, as in the subsequent example.

**Example 3: Press-Brake Forming of Corrugations.** The corrugated sheet shown in Fig. 9 was formed one at a time in a press brake, using tools shown. Dimensions given in inches.

The corrugations were made one at a time by air bending in the tooling shown at lower right in Fig. 9. Pilot holes in the workpiece and locating pins in the punch helped to keep the workpiece aligned. Deviation from flatness in the pieces was corrected by restriking some of the bends.

Irregular contours on long, narrow parts are conveniently produced by bending in a press brake. Because of the strength of stainless steels, the forming often must be divided among several successive operations, as in the subsequent example.

**Example 4: Forming of Stainless Steel Handrails in a Press Brake.** Figure 10 illustrates the shapes produced in five successive operations that were required for forming a handrail from 1.57 mm (0.062 in.) thick type 304 stainless steel. Because of flatness requirements and the resistance of the metal to bending, a 3600 kN (400 tonf) press brake was used.

Forming the 1.6 mm (0.063 in.) radius beads (operation 1, Fig. 10) was particularly troublesome because of the difficulty in retaining flatness. A force of 5300 kN (600 tonf), which

**Table 3 Typical bending limits for six commonly formed stainless steels**

Type	Minimum bend radius		
	Quarter hard, cold rolled		
	Annealed to 4.75 mm (0.187 in.) thick (180° bend)	To 1.27 mm (0.050 in.) thick (180° bend)	1.30–4.75 mm (0.051–0.187 in.) thick (90° bend)
301, 302, 304	$1/2t$	$1/2t$	$1t$
316	$1/2t$	$1t$	$1t$
410, 430	$1t$	...	...

*t*, stock thickness

**Fig. 7** Adjustable press-brake die for forming  $180^\circ$  bends in stainless steel sheet. Setup can be used for forming bends to 3.2 mm (0.125 in.) inside radius in sheet 0.30 to 0.46 mm (0.012 to 0.018 in.) thick, and it will produce 4.0 mm (0.157 in.) radius bends in half-hard stainless steel. Detachable side of die can be shimmed for bending thicker sheet or for bending with larger-radius punches. Dimensions given in inches

**Fig. 8** Production of a U-shaped bracket from a developed blank by preforming, and restriking to set flange angles, in a press brake. Dimensions given in inches

**Fig. 9** Corrugated sheet in which corrugations were formed one at a time in a press brake, using tools shown. Dimensions given in inches

exceeded the rating of the press brake, was used to form the beads.

The second and third operations presented no problems, but the fourth operation was difficult because the workpiece had to be held without marring the polished surface. Similar parts were produced from low-carbon steel without difficulty.

## Press Forming

Stainless steels are press formed with the same kind of equipment as that used in the forming of low-carbon steel. However, although all stainless steels are not the same in strength or ductility, they all need more power to form than carbon steels do. In general, presses should have the capacity for 100% more ram force than that needed for equivalent work in low-carbon steel, and frames should have the rigidity and bulk necessary to withstand this greater force.

**Dies.** In addition to wearing out faster, dies may fracture more readily when used with stainless steel than when used with low-carbon or medium-carbon steel. This is because of the greater forces needed for the working of stainless steel.

For the longest service in mass production, the wearing parts of the dies should be made of carbide, D2 tool steel, or high-strength aluminum bronze. Carbide can last ten times as long as most tool steels, but it is more expensive and does not have the shock resistance of tool steels and aluminum bronze. Tool steels such as D2 are preferred when resistance to both shock and wear is required.

Aluminum bronze offers the most protection against galling and scuffing of the workpiece. An oil-hardening tool steel such as O2 can be used for short production runs.

**Austenitic Alloys.** Workpieces can be stretched by applying high blankholder pressures to the flange areas to prevent metal from flowing into the die. This causes severe thinning, but work hardening may cause the thinned metal to be as strong as or stronger than the thicker

unworked sections. Figure 11 shows a section of an automobile wheel cover made of type 301 stainless steel; the central portion was purposely thinned and work hardened by stretching. In the following example, one of the principal reasons for stressing the workpiece to the limits of formability was to work harden it for increased strength.

**Example 5: Severe Forming for Intentional Work Hardening.** The material for a muffler header (Fig. 12) for a small aircraft engine was intentionally stressed nearly to the limits of formability to increase rigidity and to impart the necessary fatigue strength. The headers were made in two operations in a 530 kN (60 tonf) open-back-inclineable mechanical press having a 127 mm (5 in.) stroke. Each operation used a tool steel die hardened to 59 to 62 HRC. Production was 400 pieces per month.

The first die (Fig. 12a) was a compound die that formed the dish of the part, formed the bead in the dish, and blanked the inside and outside diameters. The blankholder at the outer edge of the workpiece was spring loaded, and a rubber pad supported the inner surface of the workpiece against the center blanking punch. The sequence was programmed so that the forming was completed before the outside and inside diameters were blanked, thus making the flange dimensions more accurate and concentric than would have otherwise been possible. Die life was approximately 20,000 pieces.

The second die (Fig. 12b) formed both the inner (stretch) flange and the outer (compression) flange. A spring-loaded pressure pad maintained the correct gripping pressure against the muffler-header body during this operation.

The blank was annealed type 321 stainless steel 0.81 mm (0.032 in.) thick, sheared to 216 mm (8½ in.) square. The bead formed in the first die was used as a locating surface in the second die. The dies were brushed with oil between pieces.

The production rate for both operations was seven pieces per minute. Setup time for the first operation was 0.17 h; for the second operation, 0.31 h.

**Stretching.** Stainless steel has high ductility but wrinkles easily in compression. Therefore, if there is a choice in the direction of metal flow

during forming, a better part is likely to be produced by stretching than by compression, as in the following example.

**Example 6: Use of Clamping Plates and Bead to Control Metal Flow.** The dome section shown in Fig. 13 was formed from a tapered blank of annealed type 302 stainless steel in a 2200 kN (250 tonf) double-action hydraulic press. It was desirable to maximize metal flow from the narrow end of the blank in order to cause stretching rather than contraction in the metal and thus avoid wrinkles.

The dies could not be oriented to let the blank lie flat, because of the necessity for forming the reentrant angle next to the lower clamping plates. Both the upper and the lower edges of the blank were held between steel plates during forming. The clamping force on each pair of plates was 320 kN (36 tonf). Because the upper plates were twice as long as the lower and two-thirds as wide, the clamping force was distributed over a larger area and could have permitted most of the metal flow from the larger end, with attendant wrinkling of the work metal. The addition of a bead to the upper clamping plates improved holding at that end and caused most of the metal flow to occur at the small end of the blank. The application of a fatty-acid-type, nonpigmented drawing compound to the lower plates further encouraged metal flow from the small end of the blank. Scrap loss because of tearing over the relatively sharp lower die radius was 3%.

**Ferritic Alloys.** The formability of ferritic stainless steels, particularly the higher-chromium types, can be improved by warm

Fig. 10 Shapes progressively produced in the five-operation forming of a handrail in a 3600 kN (400 tonf) press brake. Dimensions given in inches

Fig. 11 Profile of a press-formed automobile wheel cover showing thinning purposely produced by severe stretching. Dimensions given in inches

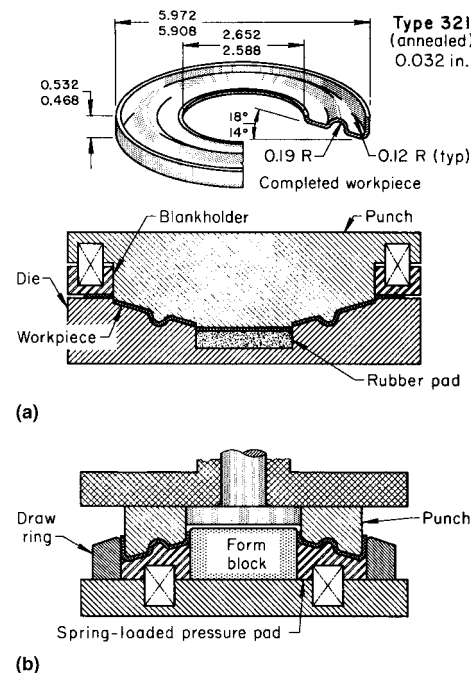

Fig. 12 Severe forming of an austenitic stainless steel aircraft muffler header to produce work hardening that would increase the rigidity and fatigue strength of the part. Dimensions given in inches

forming at 120 to 200 °C (250 to 400 °F), rather than cold forming. The metal is more ductile at the higher temperatures, and less power is needed in forming. Some pieces that cannot be made by cold forming can be successfully made by warm forming. As discussed earlier, with ferritic stainless steels the presence of cold work raises the alloy DBTT. Such cold work can promote brittle fractures in multiple forming operations, particularly if the forming sequence is interrupted and the partially formed part is allowed to cool off. Keeping heat in the part is important in multiple forming operations of thicker and higher-alloyed ferritic stainless blanks.

**Lubrication.** The lubricant used most often in the press forming of stainless steel is the chlorinated type. It has unexcelled chemical EP activity, and the ability to adjust this activity and viscosity independently over an extremely wide range makes it the most versatile lubricant for this purpose. All chlorinated lubricants are readily removable in degreasers or solvents, and emulsifiers can be added to them for easy removal in water-based cleaners.

As shown in Table 2, pigmented pastes, sulfurized or sulfochlorinated oils, and dry wax or soap-borax films are also highly effective lubricants for press forming but are less convenient to use. Heavy-duty emulsions, because of their superior characteristics as coolants, are preferred for high-speed operations. In the following example, high chlorine content and high viscosity were needed to produce acceptable parts (see also example 15, in which a low-viscosity chlorine-base lubricant replaced a viscous mineral oil).

**Example 7: Increase in Chlorine Content and Viscosity of Lubricant that Improved Results in Forming.** A wheel cover was made from a type 302 stainless steel blank, 457 mm (18 in.) in diameter by 0.71 mm (0.028 in.) thick, in two operations: draw, then trim and pierce. At first, a lightly chlorinated oil (10% Cl) of medium viscosity (1500 SUS, Saybolt Universal seconds, at 40 °C, or 100 °F) was used in drawing. Even though the draw was shallow, 12% of the wheel covers were rejected for splits and scratches.

A change was made to a highly chlorinated oil (36% Cl) of much higher viscosity (4000 SUS at 40 °C, or 100 °F). As a result, the rejection rate decreased to less than 1%. After forming, the wheel covers were vapor degreased.

## Combined Operations in Compound and Progressive Dies

The use of compound and progressive dies for the mass production of parts that require many operations or for an operation that is too severe to be done economically in a single-operation die is discussed in the article "Forming of Carbon Steels" in this Volume. The same principles apply to their use on stainless steel for blanking, piercing, bending, forming, drawing, coining, embossing, or combinations of these operations.

**Table 5 Production rates and labor time for making a severely drawn shell**

Operation	Production, pieces/h	Labor/100 pieces, h
Blank and draw(a)	922	0.108
Restrike(a)	1429	0.070
Pierce center hole; trim(b)	845	0.118
Pierce side holes(c)	786	0.127

**Fig. 13** Tools and clamping plates for controlling metal flow in press forming the part shown. Dimensions given in inches

Both compound and progressive dies must be made of die materials that are hard enough to withstand the most severe demands of blanking and are tough enough for the most severe forming or coining operations. The lubricant must have enough body for the most severe draw, yet must be light enough not to interfere with the production of coined or embossed details or to gum up cutting edges. In a compound die in a double-action press, two draws can be made in stainless steel if the press capacity is not exceeded. The following example demonstrates the near-maximum severity of forming that can be achieved in a blank-and-draw compound die.

**Example 8: Blanking and Severe Drawing in One Operation in a Compound Die.** The shell illustrated in Table 5 was blanked and drawn in a severe forming operation in a compound die at the rate of 16,000 pieces per year. The die was used in a 400 kN (45 tonf) mechanical press with an air cushion. The formed piece was restruck in the same die to sharpen the draw radius and to flatten the flange within 0.15 mm (0.006 in.). The die was made of A2 tool steel and had a life of 50,000 pieces per grind. An emulsified chlorinated concentrate was used as a lubricant.

After forming, the piece was then moved to a 200 kN (22 tonf) mechanical press, in which the 2.4 mm (0.093 in.) diameter hole was pierced and the flange was trimmed to an oval shape. A second piercing operation, in a horn die in a 200 kN (22 tonf) mechanical press, pierced two 1.6 mm (0.062 in.) diameter holes in the side of the shell. Air ejection was used in all operations except the final piercing, where the piece was picked off.

The material was type 302 stainless steel, 0.94 mm (0.037 in.) thick and 57 mm (2 1/4 in.) wide, which had been annealed. Table 5 lists the production rate and labor time for each of the four operations.

**Small, complex parts** that must be made in large quantities are well suited to production in progressive or transfer dies. A transfer die uses a minimum of material and can accept coil stock, loose blanks, or partially formed parts. Scrap removal problems are lessened. A progressive die is preferred when the piece can remain attached to the strip.

In the following example, piercing, blanking, and forming were combined in a seven-stage progressive die. Although progressive, it was hand fed—a rather unusual combination.

**Example 9: Producing a Small Bracket in a Progressive Die with Hand Feeding.** The small bracket shown in Fig. 14 was made in a seven-station progressive die from 9.5 mm (0.374 in.) wide stock that was hand fed into the 50 kN (6 tonf) press. Hand feeding was done because close operator attention was required to prevent jamming, which would have damaged the frail dies. The sequence of operations was as follows:

- Feed strip to finger stop; pierce
- Feed to notch-die opening; pierce

- Notch and trim lugs
- Form lugs
- Form and cut off
- Unload by blast of air

The parts were barrel finished to remove burrs and to provide a smooth finish and high luster. The production rate was 2175 pieces per hour. Annual production was 2 million pieces. A chlorinated and inhibited oil was used as a lubricant.

**Progressive Dies versus Simple Dies.** There is often a choice as to whether a stainless steel piece is to be made in a progressive die or in a series of single-operation (simple) dies. Deep forming usually presents difficulties in designing and constructing efficient and long-life progressive dies. The cost and delay involved in developing progressive tooling was justified for producing the frame described in the following example in quantities of 100,000 or more per year.

**Example 10: Use of Progressive Dies for High-Quantity Production of Frames.** The frame shown in Fig. 15 was made of 0.56 mm (0.022 in.) thick type 430 stainless steel coil

**Fig. 14** Bracket that was made by hand feeding stock into a progressive die to avoid the jamming that would have been likely from automatic feeding. Dimensions given in inches

stock, 95.3 mm (3 $\frac{3}{4}$  in.) wide. The maximum hardness was 83 HRB.

A nine-station progressive die was used to pierce and flange the holes, to emboss the stiffening beads on the two legs, to trim and form the tabs, to coin identification data, and to blank the part from the strip. Stops were then lanced and formed, and bottom flanges were formed in a forming die. A final forming die was used for the deep side flanges.

The progressive die was run in a 670 kN (75 tonf) mechanical press at a rate of 5000 pieces per hour. The first and second forming dies were run in a 270 kN (30 tonf) press at speeds of 984 and 936 pieces per hour, respectively.

Annual production was 90,000 frames, and demand was expected to increase. This, in addition to the short press time (0.2284 h per 100 pieces, as against an estimated 0.6665 h per 100 pieces if produced in eight separate dies) and the greater accuracy obtainable in the progressive die, justified the higher tooling cost for the progressive-die method (60% higher when compared to separate dies).

The dies were made of A2 tool steel and had a life of 50,000 to 75,000 pieces between regrinds. The lubricant was an emulsifiable chlorinated oil concentrate.

## Multiple-Slide Forming

Small high-production stainless steel parts can sometimes be formed in multiple-slide machines with the same kinds of tools as those used for the forming of low-carbon steel. Additional information is available in the article "Forming of Steel Strip in Multiple-Slide Machines" in this Volume. The following example describes the forming of a link for a flexible expanding wristband.

**Example 11: Multiple-Slide Forming of a Wristband Link.** The workpiece shown in

Fig. 16, a link for an expanding wristband, was formed in a multiple-slide machine from stainless steel strip 0.25 mm (0.010 in.) thick by 8.99 mm (0.354 in.) wide, and it was locked in shape by bent lugs. The production rate was 6000 pieces per hour.

The blank for the link was made in a five-station progressive die mounted in the press station of the machine. As shown in the upper right corner of Fig. 16, the strip was notched in stations 1, 2, and 3 by four small heeled punches. For support against side thrust, the heels entered the die before engaging the stock. An air blast entering through holes in the punches removed the scrap in order to protect the die and the feed mechanisms. In the fifth die station, two lugs on the blank were bent 60°. Spring-actuated lifters stripped the blank from the bending section of the die after the lugs were bent. The workpieces were held together by a narrow strip of stock that was left to index the workpiece through the stations of the progressive die.

The blank was then fed to the forming station so that it was edge-up between the center post (7) and the front tool (6), as shown in position A in Fig. 16. As the blank entered the forming station, the center post moved upward into the forming position. The shear blade (1) then moved forward against the fixed die (2) to trim off the joining strip. The shear blade (1) also bent the end of the blank against the auxiliary rear tool (3), which then retracted. The other end of the blank was cut off by the shear blade (4) against the die (5).

After the blank was cut off by the shear blade (4), the front tool (6) bent the workpiece around the center post (7), as shown in position B in Fig. 16.

In position C in Fig. 16, the workpiece was formed on the center post by the side tools (8 and 9) while still being held by the front tool (6). The front tool was wide enough to form the full width of the workpiece, including the lugs, but the side

**Fig. 15** Frame produced in a nine-station progressive die in the sequence of operations indicated on the strip development shown. Final forming was done in separate dies. Dimensions given in inches

tools (8 and 9) were narrower, leaving exposed the top and bottom lugs that had been formed in the last press-die station.

In position D in Fig. 16, the front and side tools (6, 8, and 9) held the part against the center post (7), while the rear tools (11) flattened the top and bottom lugs against the center post. The center post was then lowered from the workpiece. The side tool (9), which was spring loaded, slid between the top and bottom tools (10), permitting them to advance to form the top and bottom lugs into a U-shape. The side tool (9) held the workpiece against the front and side tools (6 and 8), while the top tools (10) tucked in the lugs.

With all the other tools holding the closed position against the workpiece, the rear tools (11) moved slightly to press the lugs closed against the top tools (10). As the tools opened, the completed link was then ejected by an air jet.

## Deep Drawing

The percentages of reduction obtainable in deep drawing range from 40 to 60% for the chromium-nickel (austenitic) stainless steels of best drawability and from 40 to 55% for the straight-chromium (ferritic) grades (percentage of reduction =  $[(D-d)/D] \times 100$ , where  $D$  is the diameter of the blank, and  $d$  is the inside diameter of the drawn piece). The amount of reduction obtainable varies greatly with the radius of the die and, to a lesser extent, with the radius of the punch nose. As the die radius decreases, the drawability decreases, as shown in Table 6 for austenitic stainless steel. Typically

used punch and die radii are five to ten times metal thickness. With the ferritic grades, the drawability and ductility usually decrease with increasing chromium content. To offset this, steels with high chromium content are often warmed moderately before drawing.

Presses used for the deep drawing of stainless steel differ only in power and rigidity from those used for low-carbon steel. Because of the higher work-hardening rate of stainless steel and its inherent higher strength, presses used for the deep drawing of stainless steel often need 100% more ram force and the necessary frame stiffness to support this greater force.

**Dies** for drawing stainless steel must be able to withstand the high force and resist galling. For ordinary service, D2 tool steel dies give a good combination of hardness and toughness. On long runs, carbide draw rings have exceptionally long life. Where friction and galling are the principal problems, draw rings are sometimes made of high-strength aluminum bronze. The following example describes an application in which the selection of tool material was critical in order to avoid scoring of the workpiece and to obtain acceptable die life in drawing.

**Example 12: Use of a Carbide Blank-and-Draw Ring.** An orifice cup, 25 mm (1 in.) in diameter by 11 mm ( $7/16$  in.) deep, was blanked and drawn in one operation. A 1.35 mm (0.053 in.) diameter orifice was pierced in the cup in a second operation. The specifications called for the sides of the cup to be free of score marks from the die. The blank was 40.0 mm (1.575 in.) in diameter, cut from 0.97 mm (0.038 in.) thick type 302 stainless steel strip 50 mm (2 in.) wide.

The blank-and-draw tooling shown in Fig. 17 was originally made of tool steel of a grade no longer used. It produced fewer than 50 pieces without scoring the workpieces. The combination blanking punch and draw ring was chromium plated in an attempt to increase its durability. Adhesion of the plating was not satisfactory; the chromium started to peel after 180 pieces had been produced. A draw ring of graphitic tool steel was then tried, but this also scored the workpieces.

Finally, a new draw ring was made of sintered carbide consisting of 81% tungsten carbide, 15%Co, and 4%Ta—a composition especially recommended for draw dies. The new ring, used with a chlorinated oil-based lubricant, withstood the heat and pressure generated by the severe blank-and-draw operation and produced mar-free parts. Maintenance was negligible, and after 3 years the carbide draw ring had produced 180,000 pieces, with little evidence of wear.

**Table 6 Effect of die radius on percentage of reduction obtainable in the deep drawing of austenitic stainless steel**

Percentage of reduction =  $[(D-d)/D] \times 100$ , where  $D$  is the diameter of blank, and  $d$  is the inside diameter of the drawn piece

Die radius(a)	Reduction in drawing, %
15t	50-60
10t	40-50
5t	30-40
2t	0-10

(a)  $t$ , stock thickness

**Fig. 16** Operations in the forming of a wristband link in a multiple-slide machine

The blanking punch-to-die clearance was 0.05 mm (0.002 in.) per side. Drawing punch-to-die clearance was 0.851 mm (0.0335 in.) plus 3° taper per side on the draw punch. The punch nose radius was 0.38 mm (0.015 in.), and the draw radius was 2.4 mm (0.093 in.).

**Effect of Worn Draw Rings.** The following example shows how the gradual wear of carbide draw rings in severe drawing affected the outside diameter of drawn shells.

**Example 13: Effect of Wear of a Carbide Draw Ring on the Diameter of a Drawn Shell.** The carbide draw ring used in deep drawing a shell for pens and pencils made more than 225,000 pieces before it was replaced. Measurements of the pieces were made at production intervals, as shown in Fig. 18.

Shortly after 225,000 pieces had been drawn, shells began to be produced that would no longer enter the "go" ring gage freely, because of wear on the draw ring. The worn draw ring, which permitted excessive springback, was replaced before the beginning of the next production run.

The shell was drawn from a blank of type 317 stainless steel 48.4 mm (1.906 in.) in diameter and 0.18 mm (0.007 in.) thick to a finished depth of 69.0 mm (2.718 in.) using chromium-plated punches. The shell was made in eight single-station dies, seven drawing and one end forming, at a rate of 600 per hour. The punches had a 2.29 mm (0.090 in.) nose radius, and the draw dies had a 90° conical entrance angle with a 1.52 mm (0.060 in.) radius blending the corners. A mixture of three parts inhibited hydraulic oil

**Fig. 17** Forming an orifice cup in a blank-and-draw die with a carbide punch and draw ring. Orifice was pierced in a second operation. Annual production was 60,000 pieces. Rate of blanking and drawing was 670 pieces per hour. Rate of piercing was 153 pieces per hour. Dimensions given in inches

and one part chlorinated oil was used as lubricant.

**Die clearance** for heavy draws is 35 to 40% greater than the original metal thickness for austenitic alloys. For the ferritic alloys, which thicken less, 10 to 15% is generally adequate.

Figure 19 shows a profile of an austenitic stainless steel drawn part that illustrates the thickening pattern observed in drawing a cup from this material. If the process is one of stretching more than of drawing, the clearances do not have to compensate for natural thickening.

Clearances of less than the metal thickness are generally not used with stainless steel, because they result in ironing (squeezing of the metal between the punch and die). The austenitic stainless steels are not suited to ironing, because their high rate of work hardening promotes scoring and rapid wear of the dies. In addition, any substantial ironing in the drawing of austenitic stainless steels greatly increases the likelihood of fracturing the workpiece.

The subsequent example describes an application in which the work metal was changed from galvanized carbon steel to a thinner ferritic stainless steel without a revision of die clearance. The resultant problems were solved by substituting an austenitic stainless steel that was better suited to the original clearance even though it had the same thickness as the ferritic steel.

**Fig. 18** Variation in diameter of a deep-drawn shell that resulted from wear of the carbide draw ring used. Dimensions given in inches

**Fig. 19** Profile of a shell drawn from an austenitic stainless steel showing variations in hardness and thickness produced by drawing. Dimensions given in inches

**Example 14: Matching Work Metal to Die Clearance.** Using the tooling shown in Fig. 20, basins were made at the rate of 10,000 to 15,000 pieces per year from galvanized carbon steel, 1.27 mm (0.050 in.) thick. The press was an 8900 kN (1000 tonf) hydraulic press with an air-over-oil pressure pad and a draw rate of 152 mm (6 in.) in 5 s. The punch, draw ring, and pressure pad for the drawing die (Fig. 20a) were hardened cast iron. Carbide inserts were used as cutting edges on the trimming punch and die (Fig. 20b). The locator on the trimming die was molded plastic, and the die plate was cast iron. Both dies were used side-by-side in the press at the same time because it had enough capacity to draw and trim in one stroke. Therefore, a finished piece was produced with each stroke of the press, using manual transfer.

To produce a more corrosion-resistant basin, type 430 stainless steel was substituted for the galvanized carbon steel. The type 430 was only 0.79 mm (0.031 in.) thick in order to minimize the increase in material costs; however, the same tooling was used because the relatively low annual quantity did not warrant the cost of retooling. Because the holddown forces were not suitable for the ferritic stainless steel, several hundred pieces out of the first run were fractured in drawing.

When the holddown pressure was adjusted to a level suitable for a ferritic stainless steel, contraction wrinkles formed where the material entered the throat of the die (Fig. 20c) because

**Fig. 20** Setups for drawing and trimming a basin. Die clearance (1.40 mm, or 0.055 in., per side) and drawing radius (6.4 mm, or 1/4 in.) were not changed when 0.79 mm (0.031 in.) thick type 430 was substituted for 1.27 mm (0.050 in.) thick galvanized carbon steel as the work metal, and wrinkles resulted in drawing. Dimensions given in inches

**Table 7 Effect of die clearance and draw ring radius on noncylindrical draws of stainless steel**

Stock thickness, <i>t</i>		Die clearance per side					
		Carbon steel		Type 430		Types 302 and 304	
mm	in.	mm	in.	mm	in.	mm	in.
1.27	0.050	1.40	0.055	1.40	0.055	2.29	0.090
0.76	0.030	0.84	0.033	0.84	0.033	1.37	0.054

Stock thickness, <i>t</i>		Draw ring radius					
		Carbon steel		Type 430		Types 302 and 304	
mm	in.	mm	in.	mm	in.		
1.27	0.050	6.4–9.5	1/4–3/8	6.4–9.5	1/4–3/8	4 <i>t</i> min	
0.76	0.030	4.8–7.9	3/16–5/16	4.8–7.9	3/16–5/16	4 <i>t</i> min	

the die clearance was too great. The corners of the blank were cropped, the viscosity of the lubricant was changed, and the holddown pressures were more closely adjusted in an effort to control wrinkling.

The data given in Table 7 for noncylindrical draws provide an explanation for the difficulties encountered in changing the work metal as well as guidance for the selection of a suitable stainless steel. According to these data, the thickness of type 430 stock that could best be formed by the die would be the same as that of the carbon steel previously formed. In addition, if the stock thickness were reduced, an austenitic steel such as type 302 could be used. The die clearance was 1.4 mm (0.055 in.) per side, and the draw ring radius was 6.4 mm (0.25 in.). Therefore, the die was suited for the 1.27 mm (0.050 in.) thick carbon steel but not for the 0.79 mm (0.031 in.) thick type 430. However, 0.79 mm (0.031 in.) thick type 302 would be closely matched to the die capacity.

A change was made to type 302 stainless steel, 0.79 mm (0.031 in.) thick, with no further difficulty. A change to 1.27 mm (0.050 in.) thick stock of type 430 may have been successful.

**Speed of drawing** has an important bearing on the success of the draw. A rate of 6 to 7.5 m (20 to 25 ft) per minute is a good compromise between the rate of work hardening and the uniform distribution of stress. With proper forming techniques, the rate of fracture at this speed is often less than 2%.

**Lubricants.** Ordinarily, both sides of the workpiece need to be lubricated for each draw. If too little lubricant is used, tools may accumulate enough heat during a production run to cause the work metal to fracture because of galling. In tests with a minimum of lubricant, failures occurred after 25 draws.

The chemical type and the viscosity of the lubricant are both important. Either chemical or mechanical EP activity (see the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume) is needed for the severe deep drawing of stainless steel.

Viscosity or pigment loading must not be too high or too low. Too thick a lubricant can cause wrinkling of compressed metal; too thin, seizing or galling. The ability to remove a lubricant readily is also important. In general, the higher

the viscosity, the more difficult the lubricant is to apply and remove.

The same characteristics that make chlorinated oils and waxes useful for the press forming of stainless steel (see the section "Press-Brake Forming" in this article) also make them useful for the deep drawing of these alloys. Table 2 lists other lubricants used in the deep drawing of stainless steel. Pigmented pastes and dry-films are also effective (and, in some cases, superior) in deep drawing.

In Example 15, changing from a viscous mineral oil to a low-viscosity mineral oil blend of a chlorinated wax eliminated wrinkling and galling. Sometimes, however, there is no substitute for the physical separation and equalization of pressure provided by pigments, as in Example 16.

**Example 15: Effect of Reducing Viscosity and Adding Chlorinated Wax to Mineral Oil Lubricant in Deep Drawing.** A coffeepot was deep drawn from a type 302 stainless steel blank, 355 mm (14 in.) in diameter by 0.81 mm (0.032 in.) thick, in two deep draws and one bulging operation. At first, the blanks were lubricated by brushing both sides with mineral oil having a viscosity of 6000 SUS at 40 °C (100 °F). The workpiece wrinkled in the first draw, and it galled in the second draw and in bulging.

The lubricant was replaced with a thinner mineral oil (viscosity: 500 SUS at 40 °C, or 100 °F) that was fortified with a chlorinated wax. The lubricant was brushed on, as before. Not only did the use of the modified lubricant eliminate the wrinkles in the first draw, but enough lubricant remained on the surface to prevent galling in the two other operations. Even though a fluid of much lower viscosity was used, the tenacity imparted by the chlorinated wax permitted the retention of sufficient lubricant for the subsequent bulging and deep-drawing operations.

**Example 16: Pigmented Paste versus Chlorinated Oil for Deep Drawing.** For easy cleaning in a vapor degreaser, highly fortified oils were specified for the deep drawing of a rectangular shell from 0.89 mm (0.035 in.) thick type 304 stainless steel. Chlorinated and sulfochlorinated oils with viscosities of 4000 to 20,000 SUS at 40 °C (100 °F) failed to eliminate

welding to the dies and splitting of the workpiece at the corners. The shell, a well for a steam table, was deep drawn from a rectangular blank measuring 760 by 585 mm (30 by 23 in.) with corners trimmed at 45°. The shell was drawn in one operation, and the flange was then trimmed. Interior dimensions of the drawn shell were 510 by 305 by 150 mm (20 by 12 by 6 in.). Bottom corners had 16 mm (0.63 in.) radii; vertical corners, 29 mm (1.14 in.) radii; and the flange, a 6.4 mm (0.25 in.) radius. The shell had approximately 3° taper on each side. The clearance between the punch and die was equal to the stock thickness.

The oil-type lubricant was replaced with a highly pigmented water-miscible fatty paste, diluted with two parts of water, which was applied to both sides of each blank by rollers. This lubricant eliminated the welding and allowed enough metal flow to prevent splitting. The drawn parts were cleaned with hot alkaline solution in a soak tank.

**Lubricant Location.** The location of the lubricant on the blank is also critical in the successful fabrication of a drawn part. Because all draws are made up of a combination of stretching and deep drawing, the lubricant location often depends on which type of forming is dominant. In a stretch condition, lubricant should especially be applied on the steel surface contacting the punch so that friction is minimized and the steel slips over the punch surface during stretching and thinning. Under deep-draw conditions, the steel surface contacting the die is definitely lubricated in order to allow ease of movement into the die cavity. However, whether stretch or deep drawing dominates, some lubricant is necessary on both steel surfaces to minimize the galling tendencies of stainless alloys.

**Drawing Cylindrical Parts.** When a part is made in several drawing operations, the amount of reduction in redrawing is related to the condition of the metal in the first drawing operation (cupping). If the material is highly stressed because of excessive blankholder pressure or because of small die radius, very little reduction can be made in the second operation.

General practice on the more formable grades of austenitic stainless steel is to allow 40 to 45% reduction in the first operation, followed by a maximum of 30% in the second operation, if the workpiece is not annealed between draws. With an anneal, the second reduction is usually 30 to 40%. On some parts, it may be preferable to spread the reduction over four draws before annealing—for example, successive reductions of 35, 30, 20, and 10%.

There is usually a decrease in drawability upon redrawing, and the greatest total reduction in a two-draw operation is most often produced by having the first-stage reduction as large as possible. During redrawing, it is advisable to use a tapered or rounded-end internal blankholder or sleeve to allow easy flow of metal into the die, as indicated in the article "Deep Drawing" in this Volume. An internal blankholder with small-radius 90° corners causes the metal to be bent

severely through two 90° bends before flowing into the die.

Optimal drawability is available at ram speeds of not more than 6 to 9 m (20 to 30 ft) per minute. Because of the strain-rate sensitivity of most stainless steels, work hardening of these alloys is minimized by slow forming.

The following example describes an application in which small shells were deep drawn in several steps to reduce the amount of work done in a single operation. Because production quantities were small, individual dies were more economical than a transfer die.

**Example 17: Seven-Step Deep Drawing of a Fountain-Pen Cap.** Fountain-pen caps of various closely related designs were made on the same production line by one blanking and cupping operation and six redraws. A flat blank of type 302 stainless steel having a hardness of 83 to 88 HR15-T was used. The first five draws were usually the same for any of the caps made on the line; therefore, to set up for a different size of cap, only the compound blank-and-cup die and the last die (or, for some caps, the last two dies) needed to be changed. As a result, the changeover time was only approximately 45 minutes.

In the first operation, which was done in a 160 kN (18 tonf) mechanical press, a compound blank-and-cup die equipped with a rubber die cushion was used to cut circular blanks from 0.267 to 0.279 mm (0.0105 to 0.0110 in.) thick strip and to draw them into a cup. To make a typical cap 90 mm (3½ in.) long by 8.55 to 8.57 mm (0.3365 to 0.3375 in.) in outside diameter, a blank 55.9 mm (2.200 in.) in diameter was cut from stock 57 mm (2¼ in.) wide and was drawn into a cup 19 mm (0.75 in.) deep by 31.8 mm (1.250 in.) in diameter (a 43% reduction in diameter). Reductions in the subsequent redraws were 27, 22, 18, 18, 16, and 15%, respectively. All except the last redraw were done in 35 kN (4 tonf) hydraulic presses with 152 mm (6 in.) strokes. The final redraw was made in a 55 kN (6 tonf) hydraulic press with a 305 mm (12 in.) stroke.

The draw dies were carbide inserts 13 to 16 mm (0.51 to 0.63 in.) thick. The die openings had a 4.8 mm (0.19 in.) radius blending with a 1.6 mm (0.06 in.) wide land. There was a 2° relief per side below the land. The high-speed steel punches had a 2.4 mm (0.094 in.) nose radius and were chromium plated for smoothness and wear characteristics. The workpiece was pushed through the die and stripped from the punch by a split stripper plate under the draw die. The strippers were closed by cam action from the press stripper rod.

Because production quantities of any one part were small, this technique was preferable to making a transfer die for each of the several caps produced on this line. Operations were set up in machines in the line as they were needed and as the machines became available.

The final draw, which was the deepest, governed the final production rate of 575 pieces per hour. However, when there was a backlog of

pieces, this operation was set up on two machines at the same time.

The blank-and-cup die made approximately 45,000 pieces before resharpening. The draw rings were used for 150,000 to 200,000 pieces before wear was too great. Dies in the first few draws were allowed to wear over a fairly wide range. As the die opening increased, clearance was maintained by increasing the thickness of the chromium plating on the punch. When the die openings were 0.10 to 0.13 mm (0.004 to 0.005 in.) oversized, the dies were replaced, and punches were returned to the original size by stripping, polishing, and replating.

The lubricant was a mixture of one part sulfur-free chlorinated oil with three parts inhibited hydraulic oil having a viscosity of 250 SUS at 40 °C (100 °F). This lubricant was furnished to all presses through a central pumping system.

Critical tolerances on these fountain-pen caps were ±0.02 mm (±0.0008 in.) on outside diameter and ±0.01 mm (±0.0004 in.) on inside diameter. Holding the clearance between the draw die and punch to 10% greater than stock thickness helped to maintain these tolerances.

**Steel Drawing Forces.** Estimates of the maximum drawing forces necessary to form cups from an austenitic stainless steel, a ferritic stainless steel, and low-carbon steel are compared in Table 8. These drawing forces, in tons of force, are based on the formula  $S\pi Dt$ , where  $S$  is the tensile strength of the metal in tons of force per square inch,  $D$  is the cup diameter in inches, and  $t$  is the metal thickness in inches.

Blankholding pressures for the austenitic alloys must be much higher than those for the ferritic types or low-carbon steels. For austenitic alloys, the pressure,  $P$ , on the metal under the blankholder is usually approximately 6.9 MPa (1.0 ksi); for the ferritic alloys, 1.4 to 3.4 MPa

(0.2 to 0.5 ksi). Thinner material and larger flange areas generally require greater pressure.

**Drawing Hemispherical Parts.** The drawing of hemispherical, or dome-shaped, parts demands special attention to blankholder pressure to prevent wrinkling because so much of the metal surface is not in contact with any die surface for most of the draw. Only the very tip of the punch is in contact with the work at the start of the stroke, and the surface between the tip and the blankholder draws or stretches free until the punch descends far enough to contact it. An undersized punch can sometimes be used to draw or stretch the blank into a preform before the dome-shaped punch makes the final draw, as in the following example.

**Example 18: Two-Stage Drawing of a Stepped-Diameter Hemisphere.** One of the critical points in the production of the vacuum-bottle top shown in Fig. 21 was the forming of the shoulder at the large end of the dome-shaped top. The stepped inside diameter of this shoulder had to be an exact fit with the body of the vacuum-bottle jacket. The pierced hole at the small end also had to be accurately formed to conform to the mouth of the inner container.

The stock was 289 mm (11.375 in.) wide annealed type 304 stainless steel strip, 1.1 mm (0.042 in.) thick. A single-action mechanical press with a spring-loaded pressure pad was used to cut 280 mm (11⅛ in.) diameter blanks from the strip, leaving 3.2 mm (0.13 in.) minimum scrap on each side of the strip.

The first draw was made in a 2200 kN (250 tonf) double-action mechanical press. The punch was 83 mm (3¼ in.) in diameter; therefore, much of the surface of the dome was drawn free (Fig. 21, operation 2). This required careful control of the blankholder pressure to prevent puckers and wrinkles. Blankholder pressure had to be adjusted for every lot of steel; it varied from

**Table 8 Force required for drawing two stainless steels and low-carbon steel of 1.27 mm (0.050 in.) thickness to various diameters**

Diameter of piece		Approximate drawing force required					
		Austenitic stainless steel, type 18-8		Ferritic stainless steel, 17% Cr		Low-carbon steel	
mm	in.	kN	tonf	kN	tonf	kN	tonf
125	5	350	39	180	20	160	18
255	10	700	78	520	59	350	39
510	20	1400	157	1040	117	700	78

**Fig. 21** Production of a stepped-diameter flanged hemisphere, in which a narrow punch was used in predrawing the dome. The piece was drawn from a 280 mm (11⅛ in.) diameter blank produced in operation 1 (not shown). Dimensions given in inches

5.5 to 6.9 MPa (0.8 to 1.0 ksi). The die radius also had to be held closely (5.2 times the stock thickness). The first draw produced a cup 175 mm (6<sup>7</sup>/<sub>8</sub> in.) in diameter with a 235 mm (9<sup>1</sup>/<sub>4</sub> in.) diameter flange.

The second draw was also made in the 2200 kN (250 tonf) double-action press. The punch for the second draw was shaped to the required inner contour of the part, including the step at the base of the dome, which was formed as the press bottomed at the end of the second draw stroke (Fig. 21, operation 3). This operation formed the dome shape of the bottle top by reshaping (mostly by stretching) the cup formed in the first draw. The metal for the cylindrical area above the step was drawn from the flange metal remaining after the first draw.

In the fourth operation, the hole in the top of the dome was pierced, and an internal stretch flange was formed around the hole. This was done with a spring-loaded piercing die, which gave sufficient resistance to let the piercing punch shear the material and then retreat under pressure from the flange-forming part of the punch. Both ends of the part were later trimmed in a lathe.

**Drawing Rectangular Parts.** During the deep drawing of a box-shaped part, the metal in the corners of the part and in the flange around the corner undergoes a change much like that which takes place when a round shell is drawn from a circular blank. Metal is compressed at the corners, and significant thickening occurs where the metal flows into the corners. The sides of the box undergo essentially no thickening, because there is no compression of the metal in the flange areas as it flows or bends over the die radius.

Clearances in the sides between the punch and die are ordinarily approximately 10% greater than the metal thickness to compensate for gage variations and to allow for metal flow. At the corners, punch-to-die clearances are similar to those used for cylindrical parts to allow for thickening.

Blankholding devices are almost always used in producing deeply recessed box-shaped parts in order to control the metal movement, particularly in the corners. The corners are under severe strain because of the intense compression of the flange metal, and most fracturing, if it does occur, takes place in the lower wall corner sections.

Punch and die radii are generally the same for rectangular draws as for circular draws. Some fabricators prefer to make the punch and die radii at the corners larger than along the sides in order to equalize the stress in the metal at the corners. The top surface of the draw die and the draw radii should be polished smooth (free of grind marks and well blended) to prevent localized retardation of metal flow with resultant uneven drawing of the metal. Burrs and bent edges on the blank often restrict metal flow or movement along the blankholder surface to such a degree that vertical wall fractures can occur.

Semideveloped blanks usually produce better results than rectangular ones. There are a number

of patterns for trimming the corners, ranging from a simple 45° trim to patterns with a carefully developed area containing the optimal volume and area of metal.

The economic success of the run is related to tool wear and scrap rate. The following example describes a combination of tool materials that has given satisfactory performance in terms of parts or draws per regrind and redress. The same tooling can be used for both drawing operations, with the draw ring reversed to present a different radius for the second draw, as in the following example.

**Example 19: Use of a Reversible Two-Radius Draw Ring for Drawing and Redrawing of a Flanged Rectangular Shell.** The flat-flanged single-sump kitchen sink shown in Fig. 22 was formed in four operations: blank, draw, redraw, and trim. Forming of the part was a combined draw-and-stretch operation. Because several different models, with drain holes in various locations, were made from the same drawn part, the drain hole was not pierced in the trimming operation but was made separately. The production rate was 50,000 to 100,000 pieces per year.

The material was annealed type 302 or 304 stainless steel coil stock 735 mm (29 in.) wide and 1.27 mm (0.050 in.) thick, with a No. 2D sheet finish. Blanks 635 mm (25 in.) long were sheared from the coil at the rate of 40 per minute in a single-action mechanical press. Corners of the blanks were trimmed at 45°, removing 50 mm (2 in.) from each edge of the blank at each corner. Clearance for this trimming was kept at less than 5% of metal thickness to minimize edge distortion and burrs.

The draws were made in a 3600 kN (400 tonf) double-action mechanical press with 2200 kN (250 tonf) available for blank holding. The draw punch was made of alloy tool steel, and the blankholder was made of alloy cast iron. The reversible draw ring (Fig. 22) was made of hard aluminum bronze and had a 19 mm (0.75 in.) draw radius on one side for the first draw and a 13 mm (0.51 in.) draw radius on the other side for the redraw. The workpiece was annealed in an inert atmosphere at 1065 °C (1950 °F) between the first and second draws and then air cooled rapidly to room temperature.

The depth of the sink after the first draw was 127 mm (5 in.); after the second draw it was 170 mm (6<sup>3</sup>/<sub>4</sub> in.). Draws were made at a punch speed of approximately 6.4 m (21 ft) per minute, with less than 2% of the workpieces fracturing.

A similar 3600 kN (400 tonf) press was used to trim the piece. Carbide inserts provided shearing edges for the trimming operation. The sink was held on a form block of molded plastic or cast iron for trimming.

The second draw operation sharpened the bottom and flange corner radii and stretched the bottom surface and the side walls to remove any loose metal. Little or no metal was drawn into the part from the flange during the second draw.

## Spinning

Stainless steel parts such as cups, cones, and dished heads can be readily formed by manual or power spinning, although more power is required than that needed for the spinning of low-carbon steel. Equipment and techniques for these processes are described in the article "Spinning" in this Volume.

**Manual Spinning.** The amount of thinning that occurs during manual spinning is related to the severity of the formed shape. A cross section is shown in Fig. 23 of a manually spun piece that thinned out to such a degree that it often fractured. This piece was excessively worked, and the midcenter area was work hardened beyond the capacity of the material, causing the workpiece to fracture. The piece was later made by press drawing the dome-shaped cup and spinning the broad flared flange.

The approximate limits of stretch in manual spinning are given in Table 9. These are for 1.57 mm (0.062 in.) thick fully annealed stock. The second stretch after annealing is approximately 8% less than the first. The amount of stretch is not necessarily uniform over the entire part; it varies with the severity of the form.

**Fig. 22** Production of a flat-flanged sink basin by drawing and redrawing (using a two-radius reversible draw ring) and trimming. Dimensions given in inches

Although 300-series stainless steels can be formed by spinning, 302, 304, and 305 can be spun to greater reductions than other stainless steels before intermediate annealing becomes necessary. All anneals must be followed by pickling to remove oxides, thus restoring the clean, smooth surface. The No. 1 strip or 2D sheet finish is best for severe applications because the metal is in the softest stress-free condition and will take the greatest amount of working. The following example demonstrates the spinability of type 305 stainless steel.

**Example 20: Four-Pass Manual Spinning of a Cone from Type 305 Stainless Steel.** The 355 mm (14 in.) diameter cone shown in Fig. 24 was produced in eight operations, including four manual spinning passes, from a 405 mm (16 in.) diameter blank of 0.94 mm (0.037 in.) thick annealed type 305 stainless steel that had a No. 2D sheet finish or a No. 1 strip finish. Other types of austenitic stainless steel could have been used, but the reduction per pass would have been lower, in proportion to the increase in rate of work hardening.

As shown in Fig. 24, the mandrels for spinning were made of wood or steel. The spinning roller was made of hardened steel. Pressure was applied to the entire blank in the first spinning pass. In the three other passes, the outer 25 mm (1 in.) of the blank was not spun. This caused the edge to thicken to 1.78 mm (0.070 in.) and helped hold the outer shape. Thinning was

greatest at the middle of the cone, to approximately 0.69 mm (0.027 in.) wall thickness (28% reduction). The surface area of the piece was increased 40%. The drastic working that accompanied the thinning and the increase in area made two anneals necessary (see sequence of operations, Fig. 24). Annual production quantity was 500 pieces.

**The 400-series stainless steels**, because of their relatively low ductility, do not adapt readily to manual spinning, especially when the deformation is severe. The high pressure of the forming tool causes wear of the work metal, resulting in early thinning and fracturing. Figure 25 shows forming speeds used for manual spinning of 400-series stainless steels.

The surface of severely spun parts is often very rough because of the action of the tools on the metal, and the production of a buffed or highly polished finish on a part spun from a 400-series stainless steel can be expensive. It is generally necessary to rough grind the material to smooth out the irregularities before polishing and buffing.

Typical stock thicknesses of stainless steel for manual spinning are 0.30 to 3.18 mm (0.012 to 0.125 in.), although stainless steels as thin as 0.13 mm (0.005 in.) and as thick as 6.35 mm (0.250 in.) have been spun by hand. The corner radius should be at least five times the thickness of the work metal. Allowance must be made in

the size and shape of mandrels for springback and for heat-induced dimensional changes.

**Power spinning** is used for severe reductions and for work that cannot be done by hand. Stainless steels in both the 300 and 400 series are readily formed by power spinning, but the low-work-hardening types 302 and 305 are superior. Much larger reductions of type 430 can be made by power spinning than by manual spinning.

Spinning can be done hot or cold, although the severe reduction accompanying power spinning may cause so much heat that the spinning that began cold becomes warm spinning. Hot spinning, done only above 790 °C (1450 °F), is commonly used for work 4.8 to 13 mm (0.19 to 0.51 in.) thick. The need for careful control of the temperature makes it difficult to hot spin metal that is less than 6.4 mm (0.25 in.) thick. Thicker stainless steel can be hot spun as easily as low-carbon steel.

Cracking at the edge is the main problem in the power spinning of austenitic stainless steels. The edge of the blank may need to be ground smooth to prevent cracking. A generous trim allowance is helpful so that the cracked edge can be cut off. Cracking and distortion can be prevented by keeping a narrow flange on the work. If the size of the spun piece is not correct after it cools (because of springback and heat expansion), the piece can be annealed and spun to size while it is still above 150 °C (300 °F).

**Fig. 23** Profile of shape, hardness, and thickness of a manually spun part that often fractured in its thinnest section. Dimensions given in inches

**Table 9** Approximate limits of stretch in the manual spinning of stainless steels 1.57 mm (0.062 in.) thick

Type	Stretch (max), %	Type	Stretch (max), %	Type	Stretch (max), %
305	45	321	35	202	25
302	40	309	30	301	25
304	40	310	30	405	25
302B	35	317	30	446	25
316	35	430	30	403	20
316L	35	201	25	410	20

These limits are for stretching during one spinning pass, after being annealed, the metal can be respun to 8% less than the first stretch.

#### Sequence of operations

1. Drill a 6.4 mm (1/4 in.) diam center hole in a 405 mm (16 in.) diam blank 0.94 mm (0.037 in.) thick.
2. Spin to 75 mm (3 in.) depth on a laminated hardwood mandrel at 300 rpm, applying manual pressure on lever and roller.
3. Spin to 125 mm (5 in.) depth on a second laminated hardwood mandrel to within 25 mm (1 in.) of edge.
4. Anneal in hydrogen atmosphere at 1040 °C (1900 °F); air cool.
5. Spin to 178 mm (7 in.) depth on a steel mandrel to within 25 mm (1 in.) of edge.
6. Anneal as in operation 4.
7. Spin to 205 mm (8 in.) depth and final shape on a steel mandrel.
8. Lathe-trim top and bottom ends to 195 mm (7 3/4 in.) final height of cone.

**Fig. 24** Production of a stainless steel cone by four-pass manual spinning. Dimensions given in inches

Considerable thinning can be produced by power spinning, as indicated by the cross section of a deeply spun vessel shown in Fig. 26. The thickness of the vessel was reduced from 1.90 to 0.66 mm (0.075 to 0.026 in.) in one spinning operation. A preformed cup 152 mm (6 in.) in diameter and 75 mm (3 in.) deep, drawn on a conventional press, was used as the starting shape. The top of the vessel is much thicker than the wall. Thickening of the rim occurred during drawing, and it remained thick because there was essentially no deformation in this region during spinning.

The surfaces of power-spun pieces are rough, and extensive finishing is required to make them smooth and bright. The spun surface is rough because the roller usually imparts a spiral or helical groove to the surface as the roller is fed into the metal while it rotates. Except for this disadvantage, power spinning is an excellent way of forming pieces from stainless steel.

**Lubricants** (see Table 2) are used to reduce friction, to minimize galling and tool drag, and to provide cooling. For manual spinning, firmly adherent lubricants are preferred; for power spinning, coolant action is more important. Lubricants containing sulfur or chlorine are usually avoided; they are difficult to remove completely and have harmful effects on heated stainless surfaces.

## Rubber-Pad Forming

Annealed austenitic stainless steels—types 301, 302, 304, 305, 321, and 347—are rubber-pad formed in thicknesses to 1.3 mm (0.050 in.). Most of the operations are straight flanging, especially in thicker workpieces. With auxiliary devices, such as wedges or rollers, pieces up to 2.0 mm (0.078 in.) thick can be formed. Flanges must be wide enough to develop adequate forming force from the unit pressure on their surface. For annealed stainless steels, the following minimum flange widths beyond the bend radius are recommended for successful forming:

Thickness		Flange width	
mm	in.	mm	in.
0.41	0.016	6.35	0.250
0.51	0.020	6.86	0.270
0.64	0.025	7.37	0.290
0.81	0.032	8.38	0.330
1.02	0.040	9.14	0.360
1.30	0.051	10.0	0.410
1.63	0.064	12.2	0.480
1.83	0.072	13.0	0.510

In quarter-hard temper, types 301 and 302 up to 0.81 mm (0.032 in.) thick can be flanged if the flange is at least 16 mm (0.63 in.) wide.

The rubber-pad forming of contoured flanges in stainless steel requires more powerful equipment than that used for flat flanges. Most forming of contoured flanges is done on annealed stainless steel, but a limited amount is done on quarter-hard stock.

**Stretch flanges** are readily formed on annealed stainless steel up to 1.3 mm (0.050 in.) thick. Rubber-pad-formed stretch flanges of thin metal are generally smoother and more accurately formed than those formed by single-action dies. Die-formed flanges often curl outward, requiring considerable hand work for correction.

The hydraulic presses used in the Guerin process develop forming pressures to 34.5 MPa (5 ksi). Narrow stretch flanges that require pressures greater than 34.5 MPa (5 ksi) are formed with the aid of auxiliary devices, such as traps and wedge blocks, that raise the forming pressure locally (see the article “Rubber-Pad Forming and Hydroforming” in this Volume).

Thin metal can be formed by means of a simple form block, but if the web is narrow, the workpiece should be protected by a cover plate to avoid distortion. The following example demonstrates the limits of rubber-pad forming of stretch flanges in stainless steel:

- The stock was quarter-hard type 302.
- The workpiece had a narrow web and therefore required the use of a cover plate in forming.

**Fig. 25** Effect of workpiece diameter and blank thickness on rotational speed for the manual spinning of austenitic stainless steel. Dimensions given in inches

**Fig. 26** Variations in hardness and thickness of a shell that was power spun from a preform drawn from stainless steel 1.9 mm (0.075 in.) thick. Dimensions given in inches

- The workpiece had external hole flanges.
- The stretch flange was only 7.9 mm (0.31 in.) wide.
- The curved workpiece was nearly 965 mm (38 in.) long.

If a stainless steel part of this shape is more than 610 mm (24 in.) long, it is almost impossible to prevent the springback of the flange material from bowing the part unless curved dies are used.

**Example 21: Use of a Curved Die with Cover Plates in Rubber-Pad Forming.** The strut shown in Fig. 27 had a 7.9 mm (0.31 in.) wide stretch flange and external 65° flanges on two lightening holes at the large end. It was rubber-pad formed from a quarter-hard type 302 stainless steel blank 0.41 mm (0.016 in.) thick.

The zinc alloy die used was made with a curve to offset the springback of the flange (Fig. 27). Right-hand and left-hand pieces were flanged at the same time in the same die. A steel cover plate protected the thin web of each piece from distortion during forming. No lubricant was used. The pressure developed by the rubber was 10.3 MPa (1.5 ksi).

**Deep Drawing.** By the rubber-pad and rubber-diaphragm processes, stainless steels in both the 300 and the 400 series can be deep drawn to greater reductions than can be achieved with conventional methods. For extremely deep sections, the lower-work-hardening austenitic types 302 and 305 are recommended.

Two characteristics of rubber-pad methods make this great depth of draw possible. The first is controlled, continuously adjustable pressure on the blankholder or holddown mechanism, and

**Fig. 27** Long narrow strut with a contoured stretch flange that was made by rubber-pad forming in a curved die with cover plates to prevent springback. Dimensions given in inches

the second is the continuously variable draw ring radius. There is no draw ring as such, but the rubber that forms around the workpiece functions as a draw ring and conforms to the radius that will apply equal pressure to the entire surface of the workpiece. This minimizes both thinning at the punch radius and work hardening as the flange metal is drawn into the cup.

Figure 28 illustrates the relatively uniform wall thickness that can be produced by drawing using the rubber-pad method. For comparison, Fig. 19 shows the much greater variation in wall thickness produced by conventional deep drawing. Additional information on deep drawing by rubber-pad techniques is available in the article "Rubber-Pad Forming and Hydroforming" in this Volume.

## Drop Hammer Forming

A wide variety of sizes and shapes can be formed in thin stainless steel by drop hammer forming. The advantages of this method include high impact energy (which often means that a piece can be formed by one blow, as compared to four or five by other processes) and suitability to low-volume and experimental production.

**Dies.** Die material for drop hammer forming is less critical than for press forming. The dies are made of steel, plastic, zinc alloy, and lead. Zinc alloy is widely used.

Punches are often made of lead because it can be cast directly on the lower die and because its weight adds energy to the stroke of the drop hammer. Although the lead is reusable, the number of pieces that can be made from each cast punch is small—approximately 200. Plastic punches and dies impart a finish to formed parts that would otherwise be difficult to obtain. Steel dies are used for high production and for coining and sizing.

Die designs are generally similar to those for press forming, with the same punch and die radii to reduce stress on the work metal. Die design for the forming of beads and methods of relieving entrapment to ensure good metal flow in drop hammer forming are also similar to those used in

press forming. A trapped-rubber technique somewhat similar to the Guerin process is described in the article "Rubber-Pad Forming and Hydroforming" in this Volume.

**Quality of Product.** The dimensions of workpieces formed in a drop hammer are less consistent than those made by other processes, because the degree of impact is subject to operator skill and because the punch can shift under localized high loads. However, springback is less pronounced in drop hammer forming than in other forming methods because of the high impact and forming speed.

**Lubrication.** The lubricants that can be used in drop hammer forming are listed in Table 2. If working is severe enough to require annealing between stages, contaminants such as graphite or sulfur (from the lubricant) or zinc or lead (from the die) must be removed from the work surface. If these contaminants are left on the surface of the stainless steel when it is heated, they can cause serious surface deterioration.

**Comparison with Press Forming.** Press forming, although done rapidly, is inherently an operation in which ram speed and holding pressures can be closely controlled; however, in drop hammer forming, the only way to form a part is by sudden impact. In some applications, production difficulties are overcome by the high rate of energy release in a drop hammer. In others, especially those in which blankholder pressure is critical, press forming produces better parts more economically if the die is properly made, as in the following example.

**Example 22: Change from Drop Hammer to Press Forming that Eliminated Wrinkling and Reduced Cost.** The tailpipe half shown at the top in Fig. 29 was originally produced in a drop hammer, using the tooling setup shown at the lower left in Fig. 29. The operation was

unsatisfactory, however, because wrinkles occurred at the intersection of the 30° risers, and six operations totaling nearly 2 min per piece were required to complete each piece.

The tools were redesigned for use in a 4400 kN (500 tonf) hydraulic press (lower right, Fig. 29). The zinc alloy die used in the drop hammer was reused in the press; to make it resistant to the abrasion of press forming with stainless steel, the die was faced off, and a low-carbon steel wear plate was installed. The 43 mm ( $1\frac{11}{16}$  in.) radius had formed well in the drop hammer with very little springback, but springback in the press made it necessary to deepen the die. This was done by inserting shims between the die and the wear plate.

The press produced pieces that were completely free of wrinkles at the rate of two pieces per minute. This was a  $1\frac{1}{2}$  min savings per piece.

The blank for both methods was annealed type 321 stainless steel measuring 510 by 610 mm (20 by 24 in.) and 0.71 mm (0.028 in.) thick. No lubricant was required for drop hammer forming; a wax emulsion was used for the press operation. Trimming after forming was done in a second press.

A drop hammer is ordinarily used for prototypes, and a press, using the prototype or improved dies, is used for mass production. If the quality of the prototype die is good, the drop hammer can be used for low production.

## Three-Roll Forming

The three-roll forming of stainless steel is, in general, similar to the three-roll forming of other metals (see the article "Three-Roll Forming" in this Volume). Springback is a major problem with austenitic stainless steels, primarily because of the large radii involved and work hardening. It is important that the equipment be set up so that the desired curvature can be made in one pass. Because of the high rate of work hardening of austenitic stainless steels, subsequent passes are sometimes difficult to accomplish and control unless heavy equipment is used. The response of annealed ferritic stainless steel to three-roll forming is quite similar to that of hot-rolled low-carbon steel.

Three-roll and two-roll formers can be put in sequence with contour roll formers to make a cross-sectional shape and to bend or coil it, all in one production line. The following example describes an application in which three-roll forming was combined with press forming and hydraulic expansion forming.

**Example 23: Use of Three-Roll Forming in the Production of a Container for Liquid.** Figure 30 shows eight of the 14 operations entailed in the production of a container for liquids by press forming and hydraulic expansion forming of a welded cylinder made from a radiused flat blank by three-roll forming in pyramid-type rolls. The six other operations are identified in the table that accompanies Fig. 30. These containers were produced in annual

**Fig. 28** Profile of a shell that was deep drawn from 0.76 mm (0.030 in.) thick stainless steel by the rubber-pad method showing the relatively uniform wall thickness obtained. Dimensions given in inches

**Fig. 29** Aircraft tailpipe half that was formed by the drop hammer and hydraulic press tooling setups shown. Dimensions given in inches

quantities of 10,000 to 100,000 pieces from annealed type 304 stainless steel coil stock 0.79 mm (0.031 in.) thick and 585.8 mm (23.06 in.) wide.

Blanking the rectangular sheets for three-roll forming gave the workpiece the uniform square edges needed for maintaining the welded seam of the tube in axial alignment. The blanking tools were hardened high-carbon high-chromium tool steel; clearance was 0.08 mm (0.003 in.) per side. The stock was lubricated for blanking and edge radiusing, but the blanks were vapor degreased before three-roll forming.

## Contour Roll Forming

Stainless steel is ordinarily contour roll formed in the annealed condition. Types 410 and 430 are usually roll formed on equipment similar to that used for carbon steel, with a No. 2 finish generally specified. Speeds are usually in the range of 7.6 to 30 m (25 to 100 ft) per minute, with the heavier gages and more difficult sections being roll formed at the slower speeds.

Stainless steels in hard tempers, such as quarter-hard and half-hard type 301, are also frequently roll formed. Increased power over that used for forming the same steels in the annealed condition is necessary because of the higher initial strength of the strip. Springback must be compensated for by adequate overbending.

Longitudinal cracking can be a problem with the hard tempers if adequate radii are not included in the design of the part.

Distortion or warpage of straight sections causes the greatest problem in roll forming the 300-series steels, particularly when the steel is thick. The distortion can be minimized by using more sets of rolls, or more passes, for greater control during each stage of bending. However, the skill of the operator is all-important in controlling distortion. Various straightening devices are usually attached or used on the last pass as the section emerges from the machine. In some applications, sections are deliberately curved.

With the chromium-nickel stainless steels, pickup on the rolls and galling of the strip sometimes occur. Highly polished rolls or bronze rolls are used with lubrication to minimize this problem when high pressure is needed. Heavy-duty emulsions containing chlorine offer the best combination of chemical EP and coolant activity (Table 2). Chlorinated oils or waxes are easy to use but are less effective as coolants. For severe forming, the cushioning effect of pigments is sometimes needed (as in the next example), as well as efficient cooling.

**Example 24: Nine-Station Contour Roll Forming of Annealed 304 Stainless Steel.** Figure 31 shows the sectional shapes progressively produced in the nine-station roll forming of a sheave track from annealed type 304 stainless steel strip 67.3 mm (2.648 in.) wide by

0.79 mm (0.031 in.) thick, with a No. 2 finish. In a tenth station, the formed track was straightened. As the track left the tenth station, it was clamped to a moving table that conveyed it to an abrasive wheel for cutoff into lengths of 3 to 6 m (10 to 20 ft). The material weighed 0.414 kg/m (0.278 lb/ft); annual production was 180 Mg (400,000 lb).

During forming, the developed width of the section measured along the neutral axis increased only 1.02 mm (0.040 in.) to 68.2 mm (2.688 in.), corresponding to only 1.5% stretch. The stretch was limited because the metal was restrained by the six pinch beads that were rolled into the strip before it was bent (stations 1, 2, and 3, Fig. 31). Each bead, 1.6 mm ( $1/16$  in.) wide by 0.8 mm (0.030 in.) deep, permitted a sharp bend at that point without tearing or breaking the steel. The 50 to 55% elongation property of austenitic 304 stainless steel made it unlikely that the metal would break in bending. The strip was rolled with the slitting burr down so that the burr was flattened by the shoulders of the bottom roll of station 2.

The forming rolls were made of hardened steel, and the straightening rolls of hard bronze, for a good finish. Rolling speed was 17 m (55 ft) per minute. The lubricant was a pigmented water-soluble oil.

**Plastic protective coatings** are sometimes applied to the strip to minimize or prevent scratches and scuffing when high pressures are used and surface finish requirements are critical. On light-gage material (especially type 430), such protection is generally unnecessary if the fabricator is experienced in processing stainless steel. A detailed discussion of the equipment and techniques employed in contour roll forming is available in the article "Contour Roll Forming" in this Volume.

### Sequence of operations

1. Blank in die, in single-action press.
2. Form edge radii on blank, in a press brake.
3. Vapor degrease, to remove lubricant used in operations 1 and 2.
4. Roll cylinder, in three-roll former.
5. Weld cylinder seam, in automatic Heliarc setup using starting and stop-off tabs.
6. Trim tabs.
7. Hammer weld to induce compressive stress, using an air hammer at 310 kPa (45 psi).
8. Restore roundness of cylinder by rerolling several times in three-roll former.
9. Form bead on one end of cylinder, in four passes in an edger.
10. Roll flange on opposite end of cylinder, in two passes.
11. Trim flange.
12. Vapor degrease.
13. Weld (Heliarc) disk to inside of flange.
14. Expand and form to final shape (30% reduction in wall thickness), in a hydraulic expansion die (final pressure: 4800 kPa, or 700 psi).

## Stretch Forming

The tools and techniques for stretch forming described in the article "Stretch Forming" in this Volume are applicable to stainless steel. Machines used for the stretch forming of stainless steel require 60 to 100% more power than that needed for similar operations on low-carbon steel of the same thickness.

Because of the abrasiveness of stainless steels, forming tools must be especially abrasion resistant. Wiping dies, wiping shoes, mandrels, and wear plates must be made of wear-resistant tool steel, carbide, or a bearing grade of bronze in order to avoid galling and welding.

Although the 300-series stainless steels are especially suitable for stretch forming because of their high work-hardening rate and ability to take large elongations, the 400-series steels are usable only for shallow stretched shapes. Type 301 is the austenitic steel that is best suited to stretch forming. Because of its high rate of work hardening, forming should be done slowly to derive maximum benefit from the ductility of type 301.

**Fig. 30** Use of three-roll forming in conjunction with press forming and hydraulic expansion forming, in the 14-operation production of a container for liquids. Dimensions given in inches

**Maximum percentages of stretch** for one-directional forming of various kinds of austenitic stainless steels are as follows:

- Annealed types 301, 302, 304, 305, 316, 321, and 347: 20% typical; possibly 30% on symmetrical and solid sections
- Quarter-hard types 301 and 302: 15% typical; possibly 20% on optimal sections
- Half-hard types 301 and 302: 5% typical; possibly 10% on optimal sections
- Full-hard type 301: possibly 2% on optimal sections

These figures should not be confused with permissible stretch in bending, nor are they the limits to which these stainless steels will stretch (which are considerably greater). Instead, these percentages, which determine the possible curvature of stretch-formed sectional shapes of stainless steel, are based on the distortion susceptibility of severely stretched stainless steel.

The upper limits can be extended by very slow stretching and forming, especially with hardened metal. In addition, to obtain maximum stretch from the harder tempers, workpieces should be carefully deburred. Automatic programming is valuable in applying continuously increasing tension to overcome the continuously increasing strength as work hardening takes place during stretch forming.

**Lubricants.** If there is little or no movement after contact between workpiece and form block, as in stretch wrapping or single-die draw forming, little or no lubricant need be used except when deformation is severe. A low-viscosity chlorinated oil or wax provides excellent chemical EP action and convenience of use. If there is considerable movement of the work metal against the dies (such as against the wiper shoe in radial-draw forming), pigmented lubricants are sometimes used. The following example describes an application in which no lubricant

was used in the stretch forming of a sharply contoured part.

**Example 25: Dry Stretch Forming of an Airfoil Leading Edge.** The leading edge of an airfoil was stretch formed dry from a type 302 stainless steel blank, 0.20 mm (0.008 in.) thick, 115 mm (4½ in.) wide, and 5.5 to 6.7 m (18 to 22 ft) long, that had been roll formed to the airfoil contour shown in section A-A in Fig. 32. The blank had been annealed before roll forming, and it was stretch formed, without further annealing, to a 7.6 m (25 ft) radius with the heel of the contour pointing out (Fig. 32).

The airfoil was stretch formed in a radial-draw former over a hard-maple form block with the airfoil contour carved into its surface (Fig. 32). Lubricant was not used, because it had previously caused local variations in friction. Time for forming was 10 min per piece with three men working. Setup time was 2 h. A typical production lot was 100 pieces.

The rolled contour had to be held within  $\pm 0.1$  mm ( $\pm 0.004$  in.) after stretch forming. The envelope tolerance on the stretch-formed shape was 0.76 mm (0.030 in.).

**Springback.** In sharply contoured pieces that have a relatively deep, wide cross section, some springback cannot be avoided, even in annealed metal. During severe stretch forming, considerably higher strength, and therefore appreciably higher elastic recovery, is developed in the more highly stressed convex surface.

Springback in regular, symmetrical sections can usually be offset by overbending the piece. Dimensional variations in workpieces are primarily caused by variations in springback, which are in turn caused by variations in mechanical properties from sheet to sheet.

If the workpiece is irregular in cross section, if preformed flanges are to be held to a certain angular position, or if the curve of the form varies in severity, springback may cause twist or irregular distortion of the workpiece. Various methods of blocking, pretwisting, or overforming are used to prevent or correct this distortion. In the following example, an asymmetrical cross section was twisted during forming to offset the twist caused by springback.

**Example 26: Use of Twisting to Compensate for Springback in Stretch Forming.** The curved channel section shown in Fig. 33 was

stretch formed from quarter-hard type 302 stainless steel strip, 1.07 mm (0.042 in.) thick, that had been preformed in a press brake. Although the channel fit closely in the groove of the form block, springback caused considerable twist in the finished piece.

Elastic recovery of the outer flange and the metal near the outer edge of the web caused buckling and twisting in the part as forming tension was released. To overcome this, the part was canted by the form block, and tension on the part was gradually increased during forming.

To establish a compensating initial reverse twist in the workpiece, spacers were added to the built-up form block to wedge the section to a 5° angle, as shown in Fig. 33. At the same time, a fiber filler strip with maple filler blocks was closely fitted into the channel to hold the cross-sectional contour. Details of the tooling are shown in Fig. 33.

The applied tension during stretch forming was 83.2 kN (18,700 lbf) at the start, 87.0 kN (19,550 lbf) at 45° bend, 90.7 kN (20,400 lbf) at 90°, 94.5 kN (21,250 lbf) at 135°, and 98.3 kN (22,100 lbf) on completion of the bend. A non-pigmented fatty acid was used as the forming lubricant. After forming, the workpiece was trimmed to a 145° arc with a band saw.

**Fig. 31** Contour roll forming of a sheave track in nine stations. Dimensions given in inches

**Fig. 32** Airfoil on which the leading edge was stretch formed to a long convex shape without lubricant in a radial-draw former

**Fig. 33** Channel section that was stretch formed from a preform produced in a press brake, and details of tooling used in stretch forming, which provided reverse twist to compensate for springback. Dimensions given in inches

**Equalizing Stretch.** In the stretch forming of sheets to a curvature in two directions (especially in stretching tempered material when the limits of stretch are very close), the quality of the product can be controlled much better if the stretch is uniform across the workpiece. One means of obtaining uniform stretch is to provide compensating contours (which are later trimmed off) at the end of the form block.

## Bending of Tubing

Austenitic stainless steel tubing can be bent to a centerline radius of  $1\frac{1}{2}$  times tube diameter. As the ratio of tube diameter to wall thickness,  $D/t$ , increases, it becomes increasingly necessary to provide both internal and external support to keep the tube from collapsing as it is bent. When  $D/t$  is greater than 30, the tube is classed as a thin-wall tube. Interlocked tooling, as well as bending machines of a greater capacity than that required for thick-wall tubes, is strongly recommended for thin-wall tubing (see the article "Bending and Forming of Tubing" in this Volume).

For the bending of stainless steel tubing, wiper dies and mandrels are often made of aluminum bronze or a chromium-plated tool steel. Lubricants for the mandrel should be fairly heavy. Viscous or pigmented oil-based lubricants containing emulsifiers for ease of removal are used. Only the very lightest of lubricants should be used between the wiper die and the tube. A thin application of very light chlorinated mineral oil can be used in some bending operations without causing wrinkling. The following example describes techniques used in the bending of stainless steel tubing.

**Example 27: Bending Difficult-to-Form Tubing into an Aerospace Component.** The bent tube shown in Fig. 34, used in an aerospace assembly, was difficult to form within the specified tolerances (dimensions within 0.25 mm, or  $\pm 0.010$  in.; angles within  $\pm 1/2^\circ$ ; and flattening of the tube at bends not more than 0.05 mm, or 0.002 in.). The piece was produced from type 304 stainless steel tubing in nine operations in the following sequence (times shown are for the production of 100-piece lots):

- Cut tubing into lengths of 160 mm ( $6\frac{1}{4}$  in.) with an abrasive cutoff wheel; deburr roughly (3 h)
- Fill each workpiece with low-melting alloy (8 h)
- Make  $160^\circ$  bend in powered draw bender; gage the bend (5 h)
- Make  $24^\circ$  bend in hand bender; gage the bend (5 h)
- Trim ends to length in a cutoff fixture using an abrasive wheel (3 h)
- Melt out the filler (6 h)
- Deburr by hand, using a grinder and a drill (3 h)
- Passivate in a chemical dip (1 h)
- Inspect 100% with gage and by rolling an accurate ball through the completed part (2 h)

Springback in bending, approximately  $5^\circ$ , was corrected by overbending to a degree established in trial bends.

## Other Forming Operations on Tubing

Stainless steel tubing can be easily flared to increase the diameter 25 to 30% if it is annealed. The diameter can be reduced by rotary swaging, or it can be increased by bulging or beading. Rubber punches are often used for this purpose, as described in the article "Rubber-Pad Forming and Hydroforming" in this Volume.

Tubing of austenitic stainless steel can be hot formed by heating to  $1175$  to  $1260^\circ\text{C}$  ( $2150$  to  $2300^\circ\text{F}$ ). Work should be halted when the tube has cooled to  $925^\circ\text{C}$  ( $1700^\circ\text{F}$ ), and the tube should then be cooled rapidly to minimize the precipitation of carbides.

Because austenitic stainless steel tubing is stronger than carbon steel tubing and work hardens rapidly, warm forming (below the recrystallization temperature) is also used on this material. The temperature for warm forming should be kept below  $425^\circ\text{C}$  ( $800^\circ\text{F}$ ) to prevent the formation of carbides.

Tubing of ferritic stainless steels, such as types 430 and 446, is less easily formed than similar tubing of austenitic stainless steels. Ferritic tubing is hot formed at  $1035$  to  $1095^\circ\text{C}$  ( $1900$  to  $2000^\circ\text{F}$ ), and forming is stopped when the tubing cools to  $815^\circ\text{C}$  ( $1500^\circ\text{F}$ ). For best results, the range from  $815$  to  $980^\circ\text{C}$  ( $1500$  to  $1800^\circ\text{F}$ ) should be avoided, because ductility and notch toughness are progressively impaired as the tube cools through that range. Hot shortness may be encountered in the upper part of the range. Tubing of ferritic stainless steels is warm formed at  $120$  to  $205^\circ\text{C}$  ( $250$  to  $400^\circ\text{F}$ ).

Steel producers have studied the cold formability of 11% Cr (409) and 17% Cr (439 or 18% Cr-Nb) tubing materials, primarily because of requests from the automotive industry to use titanium- or titanium-plus-niobium-stabilized ferritic alloys in exhaust systems. Such alloys are normally used in high-frequency welded, laser welded, or gas tungsten arc (GTA) welded (autogenous) and annealed tubing. Traditionally, the GTA welded and annealed tubes had more

**Fig. 34** Aerospace component that was bent from stainless steel tubing with the use of a low-melting alloy as a filler during bending. Dimensions given in inches

formability because of the elimination of the 8 to 15% cold work induced in forming the tube.

As these ferritic alloys were subjected to the demands of high-speed vector bending, particularly in making tubular exhaust manifolds, breakage rates increased to over 50%. In response, stainless steel producers borrowed technology from low-carbon steel production practices and developed a line of high-performance ferritic alloys with improved elongations and higher  $r$ -values (1.4 or above). Additional information on the determination of  $r$ -values is available in the article "Formability Testing of Sheet Metals" in this Volume.

Such alloys have permitted the greater use of high-frequency welded and unannealed tubes for thin-wall bends with a centerline bend radius less than twice the tube diameter. Furthermore, such bends can be made at room temperature, although care should be exercised in cold weather not to fabricate sub-room-temperature tubing. Finally, through tighter control of both melt chemistries and processing parameters, ferritic tube alloys with excellent welding and bending reproducibility from heat to heat have been developed.

## Forming versus Machining

Although forming ordinarily requires expensive tooling and bulky equipment, it is a high-speed process, and for most parts that can be formed from sheet, it is more economical than machining for mass production. The following example shows how production techniques can vary with the size of the production lot to make the best use of each technique.

**Example 28: Influence of Change in Quantity of Production Method and Product Design.** A threaded cap was made of type 347 stainless steel by three different methods. Each method involved a change in design, as illustrated in Fig. 35.

**Fig. 35** Machining versus press forming for producing a cap. In method A, the cap (illustrated above) was completely machined from bar stock. In method B, the cap (redesigned) combined components that were press formed from sheet and machined from bar stock. In method C, the entire cap (again redesigned) was press formed from sheet and then partly machined. Dimensions given in inches

The original order was for 100 caps, with an anticipated design change on future orders. The quickest and most economical production method was to machine the cap in one piece from bar stock (Fig. 35, method A).

The next order was for 1000 caps. The design and manufacturing methods were revised so that the cap was produced as an assembly of two components, one press formed from sheet and

the other machined from bar stock (Fig. 35, method B).

When requirements increased to 5000 caps, a cost reduction was essential to obtain the order against a competitor's bid. The part was redesigned for production entirely from sheet by press forming and partial machining (Fig. 35, method C). Overall cost was reduced nearly 50% as compared to methods A and B.

The press-formed part of method B was made in a 400 kN (45 tonf) open-back-inclinable mechanical press at a rate of 200 to 250 pieces per hour. The die was made of oil-hardening tool steel. Method C used an air-hardening tool steel die and a 530 kN (60 tonf) open-back-inclineable mechanical press that made 300 to 350 pieces per hour. Mineral oil was used as a lubricant in both methods.

# Forming of Aluminum Alloys

Revised by Pawel Kazanowski, Hydro Aluminum Cedar Tools

ALUMINUM and its alloys are among the more formable materials of commonly fabricated metals. There are, of course, differences between aluminum alloys and other metals in the amount of permissible deformation, in some aspects of tool design, and in details of procedure. These differences stem primarily from the lower tensile and yield strengths of aluminum alloys, their lower modulus of elasticity, and their comparatively low rate of work hardening as compared with typical draw-quality steels. Some aluminum alloys also have a low and even negative strain-rate hardening factor, making them significantly more sensitive to problems related to careless die design. Formability is also a function of the wide range of compositions and tempers available in aluminum alloys. This article emphasizes those aspects of commercial forming processes and equipment that apply specifically to aluminum alloys. More general information on the forming of metals is given in other articles in this Volume.

## General Formability Considerations

One aspect of the formability of a material is the extent to which it can be deformed in a particular process before the onset of cracking, splitting, or buckling. Another major aspect of formability relates to the consistency of producing nominally identical parts in sufficient quantity. Variation in yield strength, strain hardening, and gage or thickness can all contribute to poor formability in a given coil or lot of material. Considerable advances have been made in the development of alloys with good formability, but, in general, an alloy cannot be optimized on this basis alone. The function of the formed part must also be considered, and improvements in functional characteristics, such as strength and ease of machining, often tend to reduce the formability of the alloy.

Aluminum alloy sheet can fail by cracking or splitting during forming by ductile fracture, with either localized or diffuse necking. Necking is governed largely by material properties such as strain hardening and strain-rate hardening and depends critically on the strain path followed by the forming process. In dilute alloys, the extent

of necking or limit strain is reduced by cold work, age hardening, gross defects, large grain size, and the presence of alloying elements in solid solution. Ductile fracture occurs as a result of the nucleation and linking of microscopic voids at particles and the concentration of strain in narrow shear bands. Fracture occurs very soon after the onset of local necking, but fracture usually occurs at larger strains than does localized necking and therefore is usually important only when necking is suppressed due to stamping geometry or tooling issues. Common examples where fracture is encountered are at small-radius bends and at severe drawing, ironing, and stretching near notches or sheared edges (Ref 1, 2).

Most sheet metal elements may also undergo complicated deformation processes. In most sheet forming operations, aluminum and aluminum alloys are susceptible to the Bauschinger effect. The effect involves stress-strain asymmetry that results in a stress-strain hysteresis loop. From the experimental results (Ref 3), it is apparent that two identical sheet metal specimens with 6111-T4 alloy can have the same final total strains but have distinctly different spring-back amounts. The reason is that their deformation histories in the space are different.

For intricate forming operations, it is necessary to use annealed (condition O) material and the final strength developed by heat treating after the forming has been accomplished. Heat treated alloys can also be formed at room temperature immediately after quenching (W temper), which is much more formable than the fully heat treated temper. The part is then aged to develop full strength. The forming operation should be performed as soon after quenching as possible, in view of the natural aging that occurs at room temperature on all the heat treatable alloys. The natural aging can be delayed to a certain extent by placing the part in a cold storage area of 0 °C (32 °F) or lower. The longer the delay to a point where maximum delay is obtained.

**Effects of Alloying Elements.** The principal alloys that are strengthened by the presence of alloying elements in solid solution (often coupled with cold work) are those in the aluminum-magnesium (5xxx) series. Aluminum and magnesium form solid solution over a wide range of compositions, and wrought alloys containing

from 0.8% to slightly more than 5% Mg are widely used. Strength values in the annealed condition range from 40 MPa (6 ksi) yield and 125 MPa (18 ksi) tensile for alloy 5005 (Al-0.8Mg) to 160 MPa (23 ksi) yield and 310 MPa (45 ksi) tensile for the strongest alloy, 5456 (Al-5.0Mg). These alloys often contain small additions of transition elements such as chromium or manganese, and less frequently zirconium, to control the grain or subgrain structure and iron and silicon impurities that are usually present in the form of intermetallic particles. Small additions of chromium and manganese raise the recrystallization temperatures and increase the tensile properties for a given magnesium content. Figure 1 illustrates the effect of magnesium in solid solution on the yield strength and tensile elongation for most of the common aluminum-magnesium commercial alloys. Note the large initial reduction in tensile elongation with the addition of small amounts of magnesium.

The reductions in the forming limit produced by additions of magnesium and copper appear to be related to the tendency of the solute atoms to migrate to dislocations (strain age). This tends to increase strain (or work) hardening at low

**Fig. 1** Correlation between tensile yield strength, elongation, and magnesium content for some commercial aluminum alloys in the annealed temper. Source: Ref 4

strains, where dislocations are pinned by solute atoms, but it also decreases strain hardening at large strains. Small amounts of magnesium or copper also reduce the strain-rate hardening, which in turn reduces the amount of useful diffuse necking that occurs after the uniform elongation. Zinc in dilute alloys has little effect on work hardening (i.e., necking), and it does not cause strain aging.

Elements that have low solid solubilities at typical processing temperatures, such as iron, silicon, and manganese, are present in the form of second-phase particles and have little influence on either strain hardening or strain-rate hardening and thus a relatively minor influence on necking behavior. Second-phase particles do, however, have a large influence on strain at fracture. The addition of magnesium promotes an additional reduction in fracture strain, because the higher flow stresses aid in the formation and growth of voids at the intermetallic particles. Magnesium in solid solution also promotes the localization of strain into shear bands, which concentrates the voids in a thin plane of highly localized strain.

Precipitation-strengthened alloys are usually formed in the naturally aged (T4) condition or in the annealed (O) condition but rarely in the peak strength (T6) condition where both the necking and fracture limits are low. Figure 2 shows the effect of a wide range of precipitate structures on some of the forming properties of alloy 2036 (Al-2.5Cu-0.5Mg). Curves similar in shape can be drawn for most of the precipitation-strengthened alloys in the 2xxx and 6xxx series.

The properties in Fig. 2 were obtained from sheet tensile specimens first solution heat treated, then aged at temperatures ranging from room temperature to 350 °C (660 °F). This produced a full range of structures from solid solution (as-quenched) through T4 and T6 tempers to various degrees of overaging and precipitate agglomeration.

Deformation of aluminum and its alloys proceeds by crystallographic slip that normally occurs on the {111} planes in the <110> directions. Large amounts of deformation at ambient temperatures lead to some strengthening through

the development of textures, the nature of which depends in part on the mode of working. In rolled sheet, the texture that is developed may be described as a tube of preferred orientation. Preferred orientations in the plane of a sheet that are associated with textures may cause a problem known as earing. Earing describes the phenomenon of small undulations that may appear on the top of drawn cups and is wasteful of material, because this uneven end of the cup must be trimmed off. Moreover, it may lead to production problems due to difficulties in ejecting parts after a processing operation. Four ears usually form because of nonuniform plastic deformation along the rim of a deep-drawn product. If the rolling texture is predominant, then ears will appear at 45° to the rolling direction of the sheet, whereas in the presence of the annealing (or cube) texture, they form in the direction of rolling and at right angles to it. If there is a desirable balance between the two textures, there will be either eight small ears or none at all (Ref 3).

## Formability Properties and Testing

To conduct a complete analysis of a formed part, the required mechanical properties, as determined by several standard tests, must be considered. These properties include those determined by tension testing and by other tests designed to simulate various production forming processes, including cup tests and bend tests. More information on the test methods briefly described here is available in the article "Formability Testing of Sheet Metals" in this Volume.

**Tension testing** is used to determine the commonly reported properties—(ultimate) tensile strength, (tensile) yield strength, and (total) elongation—as well as two properties especially important in forming (Ref 1), that is, the strain-hardening exponent  $n$  and the plastic-strain ratio  $r$ .

The strain-hardening exponent  $n$  of a material is determined from the true stress-true strain curve for that material using the formula:

$$\sigma = K\epsilon^n \quad (\text{Eq } 1)$$

where  $\sigma$  is true stress,  $\epsilon$  is true strain, and  $K$  is a strength coefficient. Equation 1 is the Holloman strain-hardening relation and is commonly used in modeling. However, strain-hardening behavior is also described by other relations (see the article "Constitutive Equations" in this Volume). For example, the Voce relation [ $\bar{\sigma} = A - B \exp(-c\bar{\epsilon})$ ] describes aluminum sheet very well (e.g., see the article "Flanging of Aluminum" in this Volume).

The plastic-strain ratio  $r$  describes the resistance of the material to thinning during forming operations and is the ratio of the true strain in the width direction ( $\epsilon_w$ ) to the true strain in the thickness direction ( $\epsilon_t$ ) of plastically strained sheet:

$$r = \epsilon_w / \epsilon_t \quad (\text{Eq } 2)$$

A standard method for determining  $r$  using a tension specimen is given in ASTM E 517. The

strain ratio (or anisotropy factor,  $r$ ) depends on orientation relative to the rolling direction of the sheet. Thus, the average value ( $\bar{r}$  or  $r_m$ ) is commonly used in modeling and practice where:

$$r_m = \bar{r} = \frac{(r_0 + r_{90} + 2r_{45})}{4}$$

where  $r_0$ ,  $r_{90}$ , and  $r_{45}$  are strain ratios parallel, perpendicular, and at 45° to the rolling direction.

The tensile properties (as well as other mechanical properties) of many aluminum sheet alloys in medium and hard tempers exhibit directional sensitivity. The test direction should be reported along with the test results. Directional sensitivity is important in the analysis of forming operations that involve bending, flange stretching, or plane straining, all of which are encountered in the forming of ribs and troughs. Orientation of the rolling direction of the sheet relative to the direction of critical strain in the part often can mean the difference between producing a good part and producing scrap.

**Simulative Tests.** For many forming operations, tests that simulate the operation are more useful and relevant than fundamental intrinsic property measurement tests. These tests subject the work material to deformation that closely approximates the production operation, including the effects of factors not present in the intrinsic tests, such as bending and unbending and friction between the work materials and die surfaces. Because these additional factors are present, simulative tests tend to be less reproducible than intrinsic tests and must be performed under carefully controlled conditions to minimize variability in the results. Simulative tests can be classified on the basis of the predominant forming operation involved: bending, stretching, drawing, and stretch-drawing. In addition, tests have been developed to measure wrinkling and the springback that occurs after bending or another forming operation.

**The Olsen cup test** is a test used to predict resistance to local necking in biaxial-stretch-forming operations. The Olsen cup test measures the maximum penetration of a 22 mm (0.875 in.) diameter hemispherical punch into a clamped flat blank (see the section "Stretching Tests" in the article "Formability Testing of Sheet Metals" in this Volume). The punch depth at failure is the Olsen cup value. The test has been used for various materials, including aluminum alloys (Ref 5).

In Europe, several methods similar to the Olsen cup test are accepted. In eastern and northern Europe, the Erichsen cup test is widely used. The Erichsen test is similar to the Olsen cup test, except that the punch diameter is 20 mm (0.790 in.). The value reported is the ratio of cup height to cup diameter when the specimen is stretched over the 20 mm (0.790 in.) diameter ball. In Great Britain, the Avery test is very common, while in France the Guillery test is employed. Both methods are very similar to the Erichsen cup test, with slight modifications to the tooling and its setup.

Historically, ball punch tests, such as the Olsen cup test and Erichsen cup test, have been

Fig. 2 Effect of precipitation on yield strength and elongation of aluminum alloy 2036. Source: Ref 4

used to determine the properties of sheet metals in stretching. However, the correlation between the test results and the steel performance in many sheet metal forming operations has not been good. These tests stretch a specimen over a hardened steel ball and measure the height of the cup produced. Tests that stretch the specimen over a much larger hemispherical dome have been developed, including the limiting dome height test, which uses specimens of different widths to control the strain ratio at fracture.

*In the Swift cup test*, a deep-drawn cup is used to determine the limiting draw ratio (LDR) of blank size to cup diameter. It is obtained with a 51 mm (2.0 in.) diameter flat-bottom punch and a draw die appropriate for the thickness of the specimen. A circular blank is cut to a diameter smaller than the expected draw limit. Lubrication is provided by two oiled polyethylene disks, one on each side of the blank. The blank is drawn to maximum punch load, which occurs before the cup is fully formed. Successively larger blanks are drawn until one fractures before being drawn completely through the die. The diameter of the largest blank that can be drawn without fracturing, divided by cup diameter, determines the LDR.

*In bend tests*, strips of material are bent around mandrels having different tip radii. Often, mandrels are in the form of pins or rods. The mandrel is forced against one side of the specimen strip, and the other side is simply supported at the end points. The value reported is the minimum radius of mandrel, in multiples of the material thickness  $t$  around which the material can be bent 180° without cracking. The direction of the bend relative to the rolling (or extrusion) direction should be recorded with the test results. Bend test results may vary significantly, depending on the test method. Bend-test methods include a guided-bend method, several semiguided methods, free-bend methods, and a bend-flatten method (ASTM E 290). Correlation of minimum bend radii with tensile-test data is discussed in the section "Bendability" in the article "Bending of Sheet Metal" in this Volume.

*Correlation of Simulative Test Results with Tensile-Test Data.* In some cases, results of simulative forming tests correlate with results of tension tests. Results of cup ductility tests, such as the Olsen and Swift tests, show good correlation with values of tensile elongation, strain-hardening exponent, and plastic-strain ratio. Olsen cup values correlate well with tensile elongation, and Swift cup values correlate with plastic-strain ratio. Neither of these two cup-ductility tests correlate with bend tests.

**Forming-limit diagrams**, also known as forming-limit curves, are direct and useful representations of the formability of aluminum sheet. These diagrams illustrate the biaxial combinations of strain that can occur without splitting. These diagrams are commonly derived from experimental testing, although computer-based modeling is an area of interest (Ref 6) due to the labor-intensive process of the experimental method.

To construct forming-limit diagrams experimentally, an array of circles, which often are 2.5 mm (0.1 in.) in diameter, is first imprinted by photoprinting, photoetching, or electroetching on the surface of the sheet metal before forming. After deformation, the imprinted circles either remain as circles in areas where pure biaxial stretching occurs or become ellipses wherever deformation is not purely biaxial stretching. The major and minor axes of the ellipses are compared with the circles of the original grid to determine the major and minor strains at each location. The areas immediately adjacent to splits are of particular concern in evaluating the forming capabilities of the metal. Failure can be defined by several criteria, but the onset of visible necking is the most widely used. The loci of strain combinations that produce failures define the forming-limit curve. The area below this curve encompasses all the combinations of strain that the metal can withstand. Forming-limit diagrams for a variety of aluminum alloys and tempers are shown in Fig. 3 to 5.

*Stress-Based Forming-Limit Curves.* A relatively new approach to refine formability theory is the stress-based forming-limit curve (FLC) developed by T. Stoughton of the General Motors Research Laboratories (Ref 8). It has been shown that the stress-based FLC is independent of strain path and is unique for a given material. Conventional FLCs are strain-based, created by stretching various-width strips of material over a smooth ball. The ball is large enough so that relatively little stress is introduced through the thickness of the material. The result is that the material is strained proportionately throughout the test.

The strain-based FLC is relevant for forming processes with a linear strain path, which is representative for most first-draw forming operations. However, a nonlinear strain path may be found in secondary forming processes, such as some restrike operations, and even in some areas of the first-draw die, such as re-entrant surfaces such as door handles on doors that have been subjected to high prestrain. In these cases, the strain path can significantly alter the FLC (see Fig. 9 in the article "Modeling and Simulation of the Forming of Aluminum Sheet Alloys" in

this Volume). Stress-based FLCs (Ref 9, 10) resolve this discrepancy that results from non-uniform strain paths.

## Equipment and Tools

Most of the equipment used in the forming of steels and other metals is suitable for use with aluminum alloys. Because of the generally lower yield strengths of aluminum alloys, however, required press capacities are usually lower than for comparable operations on steel, and higher press speeds can be used. Similarly, equipment for roll forming, spinning, stretch forming, and other forming operations on aluminum need not be as massive or rated for such heavy loading as for comparable operations on steel. The lower elastic modulus leads to greater springback, which thus requires different die designs than for steel forming.

The forming of aluminum (1100) is relatively easy, using approximately the same procedures as those used for common steel, except that care must be taken to prevent scratching. Do not mark on any metal surface to be used as a structural component with a graphite pencil or any type of sharp, pointed instrument. All shop equipment, tools, and work area should be kept smooth, clean, and free of rust and other foreign matter. Alloyed aluminum (2024, 7075, 7178, etc.) is

Fig. 4 Forming-limit diagrams for four 5xxx-series aluminum alloys. Source: Ref 7

Fig. 3 Forming-limit diagrams for two 3xxx-series aluminum alloys. Source: Ref 7

Fig. 5 Forming-limit diagrams for aluminum alloys 1100-H19 and 6061-T4 and for Al-6Mg. Source: Ref 7

more difficult to form, and extensive control is required to prevent scratching and radii cracking. Scratching will make forming more difficult, plus it provides an easy path for corrosion attack, especially on clad materials.

**Tools.** Total wear in forming aluminum is somewhat less than that of steel. This results in part from the lower force levels involved and in part from the smoother surface condition that is characteristic of aluminum alloys. Accordingly, tools can sometimes be made from less expensive materials, even for relatively long runs.

However, a higher-quality surface finish is generally required on tools used with aluminum alloys, to avoid marking. The oxide film on the surface of aluminum alloys is highly abrasive, and for this reason many forming tools are made of hardened tool steels. As a rule, these tools, even if otherwise suitable, should not be used interchangeably to form steel parts, because this could destroy the high-quality finish on the tools.

Most aluminum alloys require smaller clearances between punches and dies in blanking and piercing than do steels. On drawing tools, they require larger clearances but approximately the same radii, to allow the free flow of metal and avoid excessive stretching.

The amount of springback in forming aluminum alloys, which is generally more than that of steel, must be considered in tool design (see the article "Springback" in this Volume). The amount of springback is roughly proportional to the ratio of yield strength to elastic modulus of a metal. Additionally, the lower rate of work hardening of aluminum alloys permits a greater number of successive draws than is usually possible with steel.

## Lubricants

Lubricants must be specifically selected for their compatibility with aluminum alloys and their suitability for the particular forming operation in question. A lubricant suitable for use on a steel part will not necessarily be suitable for use in the forming of a similar aluminum alloy part.

The proper formulation of lubricants for the forming of aluminum alloys must take into account the special requirements of regulation of moisture content in nonaqueous systems, corrosion inhibitors, and pH control, in order to prevent staining or corrosion and to make duration of contact with the workpiece less critical.

The lubricants most widely used in the forming of aluminum alloys are listed in approximate order of increasing effectiveness:

- Kerosene
- Mineral oil (viscosity of 40 to 300 SUS at 40 °C, or 100 °F)
- Petroleum jelly
- Mineral oil plus 10 to 20% fatty oil
- Tallow plus 50% paraffin
- Tallow plus 70% paraffin
- Mineral oil plus 10 to 15% sulfurized fatty oil and 10% fatty oil

- Dried soap films or wax films
- Fat emulsions in aqueous soap solutions with finely divided fillers
- Mineral oil with sulfurized fatty oil, fatty oil, and finely divided fillers

The use of various special-purpose lubricants is discussed in sections of this article that deal with individual forming processes. The article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume contains more information on lubricants for sheet forming.

## Blanking and Piercing

Blanking and piercing of aluminum alloy flat stock are ordinarily done in punch presses because of their high production rates and ability to maintain close tolerances. Press brakes are sometimes used, particularly for experimental or short-run production.

The generally lower shear strength of aluminum alloys usually permits the use of presses or press brakes of lower capacity than those used for comparable operations with steel. A conservative (high) calculation of the required shearing force is the product of shear strength times the total length of cut and metal thickness. This calculation will give high force requirements, because the shear action is not typically applied to the whole circumference simultaneously. Allowance also must be made for different alloys, for dulling of the cutting edges of punches and dies, and for variation in clearance between punch and die. The shear strengths of the commonly used aluminum alloys range from 62 to 338 MPa (9 to 49 ksi), whereas the shear strength of a typical low-carbon steel is 240 to 460 MPa (35 to 67 ksi).

**Tool Materials.** A discussion of materials for blanking and piercing dies is given in the article "Selection of Materials for Press-Forming Dies" in this Volume. Aluminum alloys are classed with other soft materials, such as copper and magnesium alloys. In general, for a given tool material, tool life is longer for blanking and piercing aluminum alloys than for blanking and piercing steel.

In some applications, a less expensive die can be used than is true for steel parts, particularly for relatively short runs. Cast zinc dies, which cost only approximately one-fifth as much as tool steel dies, are used for runs of up to approximately 2000 parts (as in forming steels). Steel-rule dies and template dies also reduce tooling costs for short runs or moderate-length runs. For example, an aluminum alloy blank 495 by 305 mm (19.5 by 12 in.) by 1 mm (0.040 in.) in thickness was made in a steel-rule die having an expected life of 150 pieces. For the production quantity, burr height did not exceed 0.127 mm (0.005 in.). Punches and die buttons for seven pierced holes of 3.9, 4.8, and 6.4 mm ( $\frac{5}{32}$ ,  $\frac{3}{16}$ , and  $\frac{1}{4}$  in.) diameter were incorporated in the die.

Low-carbon steel or cast iron dies sometimes replace hardened tool steel dies, even for long

runs. Punches are usually made from annealed or hardened tool steel, depending on the size and complexity of the part and the length of the run. Cemented carbide tools are seldom required, even for extremely long runs.

**Tolerances.** A tolerance of  $\pm 0.127$  mm (0.005 in.) is normal in the blanking and piercing of aluminum alloy parts in a punch press. Using a press brake, it is possible to blank and pierce to a location tolerance of  $\pm 0.25$  mm (0.010 in.) or less, although tolerances for general press brake operations usually range from  $\pm 0.51$  to  $\pm 0.76$  mm (0.020 to 0.030 in.).

For economy in tool cost, specified tolerance should be no less than is actually necessary for the particular part. A tolerance of  $\pm 0.127$  mm (0.005 in.) would probably require that the punch and die be jig ground, adding 30 to 40% to their cost. A tolerance of  $\pm 0.05$  mm (0.002 in.) may require the addition of a shaving operation. In addition to the cost of an extra die, labor costs would be increased by the added operation.

For extremely accurate work, an allowance must be made for the shrinkage of holes and expansion of blanks resulting from the elasticity of the stock. This allowance, made to both punch and die, does not change the clearance between them, and is primarily a function of stock thickness. For large sizes and normal tolerances, this correction is not very important.

**Clearance between punch and die** must be controlled in blanking and piercing in order to obtain a uniform shearing action. Clearance is usually expressed as the distance between mating surfaces of punch and die (per side) in percentage of work thickness.

Correct clearance between punch and die depends on the alloy as well as the sheet thickness. Suggested punch-to-die clearances in terms of percentage of sheet thickness  $t$  for blanking and piercing aluminum alloys in various tempers are listed in Table 1.

The character of the shearing action also depends on the sharpness of the tools. Dull cutting edges on punch and die have effects similar to those of excessive clearance, with the effect on burr size being particularly pronounced.

With proper clearance, the fractures proceeding from the punch surface and from the die surface of the work meet cleanly without secondary shearing and excessive plastic deformation. Secondary shearing indicates that the clearance is too small; a large radius or dished contour at the sheared edge and a stringy burr indicate that the clearance is too large.

Blanking tools are generally assigned with less clearance than piercing tools, so that the burnished area of the piece part (slug) is greater. For typical aluminum alloy and sheet thickness greater than 5 mm (0.2 in.), piercing clearance should be 5% higher than blanking clearance. This leads to a higher-quality piece part; however, due to the smaller clearances, blanking tools become dull more quickly.

**Die Taper.** The walls of die openings in blanking or piercing dies are often tapered  $\frac{1}{2}^\circ$  from the vertical, to minimize sticking of the

blank or slug in the die. A straight, vertical section of at least 3.2 mm (1/8 in.) or equal to the metal thickness for stock thicker than 3.2 mm (1/8 in.) is usually left at the upper end of the die opening, to provide for sharpening without changing the clearance. Tapered die relief is usually more suitable for piercing aluminum than is counterbore design relief.

**Stripping force** of 3 to 20% of the total capacity needed for blanking and piercing is used for aluminum alloys. The force needed depends on the alloy, temper, and stock thickness. Sharpness of cutting edges on punch and die,

lubrication, and uniformity of application of stripper-plate pressure also affect stripping force.

**Lubricants** are normally used in blanking or piercing aluminum alloy parts to reduce sticking of slugs or blanks in the die opening and to facilitate clean stripping from the punch without buckling. Lower tool maintenance costs and smoother edges on blanks or holes can be obtained with suitable lubrication.

## Forming Using Tailor-Welded Blanks

A promising approach to reduce manufacturing costs, decrease vehicle weight, and improve the quality of automotive body components is through the use of tailor-welded blanks. This term refers to blanks where multiple sheets of material are welded together to create a single blank prior to the forming process. The welding process creates formability concerns in a traditional forming process due to material property changes in the weld and in the heat-affected zone adjacent to the weld. Tailored blanks are also produced by roll forming of blanks with tailored variation of section thickness in desired locations.

In the conventional fabrication of automobile body component assemblies, several stampings are formed individually and subsequently spot welded together in order to obtain the material and strength requirements at various locations in the assembly. Alternatively, the various materials can be welded together prior to the forming process to produce what are known as tailor-welded blanks (TWBs). This term is derived from the notion that the automobile designer will be able to tailor the location in the stamping where specific material properties are desired. These differences can be in the material grade, gage thickness, strength, or coating, for example, galvanized versus ungalvanized (Ref 11).

Forming of TWB steel is described in more detail in the article "Forming of Steel Tailor-Welded Blanks" in this Volume. The production of aluminum TWBs involves:

- Blanking aluminum alloy sheet into desired sizes and orientations
- Cleaning the material
- Precisely positioning the materials relative to each other
- Welding the sheets together into a single flat sheet

Each step in the process is considered critical to avoid excessive gap between sheets prior to welding and to prevent or eliminate contamination on the sheet that may result in a weld imperfection (Ref 12). The TWBs began appearing in Europe and Japan in the mid-1980s, and their use has continued to increase. Forty to sixty million TWBs were produced in 2000 (Ref 13).

The TWBs have generated enormous interest in the automotive industry as of late, due to the substantial benefits they produce. These include:

- Reduced manufacturing costs due to fewer forming dies
- Elimination of downstream spot-welding operations
- Reduced scrap; weight reductions due to the combining of parts into a single component; improved dimensional part consistency from the reduction of inaccurate spot-welding processes
- Improved corrosion resistance through the elimination of lap joints by integration of reinforcements (Ref 11)
- Improved crash test results due to the increased stiffness of laser and mash-seam welds in comparison to traditionally used spot welds

However, because the material properties in the heat-affected zone (HAZ) adjacent to the weld and in the weld itself are significantly less desirable from a forming standpoint compared to those of the base metal, creating a failure-free deep-drawing process for TWBs is difficult. While there are not specific published studies on the formability of aluminum in TWB applications, the effects on the mechanical properties of welding aluminum alloys has been studied (Ref 14).

Aluminum has several chemical and physical properties that need to be understood when using the various joining processes. The specific properties that affect welding are:

- Aluminum oxide characteristic
- Solubility of hydrogen in molten aluminum
- Aluminum thermal, electrical, and non-magnetic characteristics
- Wide range of mechanical properties and melting temperatures that results from alloying with other metals (Ref 14)

Significant reductions in the potential elongation, both transverse (i.e., perpendicular) and longitudinal (i.e., parallel), to the weld line have been reported. In addition, unlike steel, the strength of aluminum in the HAZ decreases due to welding (Ref 14). For a 6xxx-series aluminum alloy, the tensile strength in the HAZ can be reduced by as much as 40% of the base metal value (Ref 14). However, this reduction varies greatly, based on the filler alloy used in the welding, postweld heat treatment or aging, and other welding process parameters, such as the amount and duration of weld heating.

When choosing the optimal filler alloy, the end use of the weldment and its desired performance must be the prime consideration. Many alloys and alloy combinations can be joined using one of several filler alloys, but only one filler may be optimal for a specific application. Table 2 (Ref 15) lists the chemical composition and melting range of standard aluminum filler alloys.

The primary factors commonly considered when selecting a welding filler alloy are:

- Ease of welding freedom from cracking
- Tensile or shear strength of the weld
- Weld ductility
- Service temperature

- Corrosion resistance
- Color match between the weld and base alloy after anodizing

Another concern in TWBs is weld-line movement. Whether produced with steel or aluminum, the stronger material in the TWB will resist deformation more than the weaker material, causing the weld line to move in the stamped part. This effect limits the ability of the designer to position the specific material properties in the

final stamping where desired and may create other forming problems, such as wrinkling, tearing, and uncontrollable springback.

Despite these formability concerns, TWBs incorporated into the automobile body were prudent to reap the potential rewards they offer. Some of the components where TWBs are currently being used are body side panels, motor compartment rails, center pillar inner panels, door inner panels, and wheel-house/shock tower panels (Ref 16, 17).

## Bending

The most common problems encountered in practice are springback and cracking within the bend area. Problems associated with bend cracking are usually a result of improper bend radii, rough edges of material being formed or the forming equipment, and bending parallel to the direction of grain flow. For the approximate bend radius to use in bending various thicknesses and types of aluminum, see Table 3. Actual practice may reveal that a larger or a smaller radius may be used in some instances. If tighter bend radii are required, then fabricators should proceed with additional caution and, if needed, should seek the assistance of engineering or laboratory metallurgists.

Difficulties encountered with springback are most commonly associated with bending of the stronger alloys, especially those having high yield strength. Springback problems associated with this material can be overcome to a certain degree by overforming. The amount of overforming used will depend on the temper and the alloy; the softer the material, the less springback compensation required. Other means of reducing springback are to bend the material in the soft condition (condition O) or immediately after quenching, and to reduce the thickness or the radius if allowed. Avoid reducing radii to the point that grain separation or bend cracking results.

## Press-Brake Forming

The press-brake forming techniques used with aluminum alloys are similar to those used with steel and other metals, differing only in some details of tool design (see the article “Press-Brake Forming” in this Volume).

**Tolerances** in press-brake forming are larger than those in punch-press operations. For simple shapes that are relatively long and narrow, a tolerance of  $\pm 0.8$  mm ( $1/32$  in.) can usually be maintained. On larger parts of more complex cross section, the tolerance may be as much as  $\pm 1.6$  mm ( $1/16$  in.).

**Springback**, or partial return to the original shape upon removal of the bending forces, occurs in most forming operations. The amount of springback depends on the yield strength, strain hardening, the rigidity of the section (which depends on the elastic modulus and the thickness of the material), and on the bend radius. Springback also depends strongly on concentration of strain and the presence of additional stress, such as in stretch bending.

Table 4 shows the effects of these variables, giving springback allowances in degrees of overbending that have been used for high-strength aluminum alloys 2024 and 7075. The springback allowance, or number of degrees of overbending required, ranges from 1 to 12° for 2024-O and 7075-O (yield strength of 76 MPa, or 11 ksi, min), and from  $7\frac{1}{4}$  to  $33\frac{1}{2}$ ° for

**Table 4 Springback allowances for 90° bends in 2024 and 7075 aluminum alloy sheet**

Sheet thickness		Springback allowance, in degrees, for bend radius, mm (in.) of:

2024-T3 (yield strength of 345 MPa, or 50 ksi). The allowance increases with increasing yield strength and bend radius but varies inversely with stock thickness. The allowance for bends of other than 90° can be estimated on a proportional basis. For bend angles of less than 90°, the springback may be greater unless the bend radius is decreased, because the metal in the bend area may not have been stressed beyond its yield point.

**Radii** to which bends can be made depend on the properties of the metal and the design, dimensions, and condition of the tools. For most metals, the ratio of minimum bend radius to sheet thickness is approximately constant, because ductility is the primary limiting factor on minimum bend radius. This is not true for aluminum alloys, for which the ratio of bend radius to sheet thickness increases with the thickness.

With special tooling, aluminum alloys can be bent to smaller radii than those indicated in standard tables. Bottoming dies and dies that combine bottoming with air bending are used for this purpose. Hydraulic forming, forming with rubber-pad dies, and high-energy-rate forming also produce good small-radius bends.

Sometimes, it is possible to take advantage of the grain direction in the work metal: The most severe bends can be made across the direction of rolling. If similar bends are made in two or more directions, it is recommended that, if possible, all bends be made at an angle to the direction of rolling. Local heating along the bend lines can sometimes be used to produce small bend radii without fracture; this is particularly useful in bending plate.

**The maximum temperature** that can be used without serious loss in mechanical properties is 150 to 205 °C (300 to 400 °F) for cold-worked material. Reheating of naturally aged aluminum alloys 2014 and 2024 is not recommended unless the part is to be artificially aged. Generally, any reheating sufficient to improve formability will lower the resistance to corrosion

to an undesirable degree, except with alclad sheet.

**Blank Development.** For relatively simple parts, particularly those for which close tolerances are not required, the blank layout can be developed directly by using bend-allowance tables or equations. As a rule, the initial calculated blank layout and die design are developed into final form by successive trial and modification.

**Lubricants** are needed for nearly all press-brake forming of aluminum alloys. The light protective film of oil sometimes present on mill stock is often adequate for mild bending operations, but when this is not sufficient, a lubricant is usually applied to the working surfaces of the tools and the bend area of the workpiece to prevent scoring and metal pickup.

**Tools.** The bending, forming, piercing, and notching dies used in press brakes for aluminum alloys are much the same as those used for low-carbon steel. To prevent marring or scratching of the workpiece, tools used for bending steel should be carefully cleaned and polished before being used for aluminum alloys. Rubber pads used in press-brake dies, when clean, will not scratch the surface of an aluminum sheet.

Because of the differences in tensile strength and springback, shut height settings for aluminum alloys may be different from those for low-carbon steel.

## Contour Roll Forming

Aluminum alloys are readily shaped by contour roll forming, using equipment and techniques similar to those used for steel (see the article "Contour Roll Forming" in this Volume). Operating speeds can be higher for the more ductile aluminum alloys than for most other metals. Speeds as high as 245 m/min (800 ft/min) have been used in mild roll forming of 0.8 mm (1/32 in.) thick alloy 1100-O sections 15

to 30 m (50 to 100 ft) long. Power requirements for roll forming of aluminum alloys are generally lower than is the case for comparable operations on steel, because of the lower yield strength of most aluminum alloys.

**Tooling.** The design of rolls and related equipment, as well as the selection of tool materials, is discussed in the article "Contour Roll Forming" in this Volume. The most commonly used material is L6 tool steel, a low-alloy nickel-chromium grade with excellent toughness, wear resistance, and hardenability. For extremely severe forming operations or exceptionally long runs, a high-carbon high-chromium grade such as D2 is preferred because it has superior resistance to galling and wear. These tool steels are hardened to 60 to 63 HRC. The tools are highly polished and are sometimes chromium plated to prevent scratching and to minimize the pickup of chips when surface finish of the work is critical.

For short runs and mild forming operations, rolls can be made of turned and polished gray cast iron (class 30 or better) or low-carbon steel. For light-gage metals, tools made of plastics reinforced with metal powder, or of specially treated hardwood, have occasionally been used. For some applications in the roll forming of light-gage alloys when quality of surface finish is the primary concern, use has been made of cast zinc tools, at the cost of shorter tool life.

Extremely close tolerances are required on tool dimensions. Allowance for springback must be varied with alloy and temper, as well as with material thickness and radius of forming, as indicated in Table 4. Final adjustments must be made on the basis of production trials.

**Tolerances** of  $\pm 0.127$  mm (0.005 in.) are common in contour roll forming, and  $\pm 0.05$  mm (0.002 in.) can be maintained on small, simple shapes formed from light-gage metals. One or two final sizing stations may be required for intricate contours or when springback effects are great.

**Lubricants** are required in nearly all contour roll forming of aluminum alloys. For high-speed or severe forming operations, the rolls and workpiece may be flooded with a liquid that functions as both a lubricant and a coolant. A soluble oil in water is preferred for this type of operation. When a more effective lubricant is required, a 10% soap solution or an extreme-pressure compound may be used. These are better suited for minimizing tool wear and producing a high-quality finish, but are more difficult to remove.

**Applications.** Roll-formed aluminum alloy parts made from sheet or coiled strip include furniture parts, architectural moldings, window and door frames, gutters and downspouts, automotive trim, roofing and siding panels, and shelving.

Tubing in sizes ranging from 20 to 200 mm (3/4 to 8 in.) in outside diameter and from 0.64 to 3.9 mm (0.025 to 0.156 in.) in wall thickness is made in a combined roll-forming and welding operation (see the article "Contour Roll Forming" in this Volume). Linear speeds of 9 to

60 m/min (30 to 200 ft/min) are used in this process. Applications include irrigation pipe, condenser tubing, and furniture parts.

Other applications of contour roll forming include the forming of patterned, anodized, or pre-enameled material. Such applications impose stringent requirements on tool design and maintenance, and lubrication sometimes cannot be used because of the nature of the coating or because of end-use requirements.

## Deep Drawing

Equipment, tools, and techniques used for deep drawing of aluminum and aluminum alloys are similar to those used for other metals and are described in more detail in the article "Deep Drawing" in this Volume. This section deals with those aspects of deep drawing that are specific to aluminum alloys and is restricted to procedures using a rigid punch and die. Other procedures are described in subsequent sections of this article.

**Equipment.** Punch presses are used for nearly all deep drawing; press brakes are sometimes used for experimental or very short runs. Presses used for steel are also suitable for aluminum.

Capacity requirements, determined by the same method used for steel, are generally lower for comparable operations because of the lower tensile strength of aluminum alloys.

Press speeds are ordinarily higher than they are for steel. For mild draws, single-action presses are usually operated at 27 to 43 m/min (90 to 140 ft/min). Double-action presses are operated at 12 to 30 m/min (40 to 100 ft/min) for mild draws, and at less than 15 m/min (50 ft/min) for deeper draws with low- and medium-strength alloys. Drawing speeds on double-action presses are approximately 6 to 12 m/min (20 to 40 ft/min) with high-strength alloys.

**Tool Design.** Tools for deep drawing have the same general construction as those used with steel, but there are some significant differences. Aluminum alloy stock must be allowed to flow without undue restraint or excessive stretching. The original thickness of the metal is changed very little. This differs from the deep drawing of stainless steel and brass sheet, each of which may be reduced by as much as 25% in thickness in a single draw.

**Clearances between punch and die** are usually equal to the metal thickness plus approximately 10% per side for drawing alloys of low or intermediate strength. An additional 5 to 10% clearance may be needed for the higher-strength alloys and harder tempers.

With circular shells, metal thickening occurs with each draw; therefore, clearance is usually increased with each successive draw. The restrictions imposed on the drawing of rectangular shells by metal flow at the corners make equal clearances for each draw satisfactory. The final operation with tapered or rectangular shells serves primarily to straighten walls, sharpen radii, and size the part accurately. Therefore, the

clearance for these operations is equal to the thickness of the stock.

Insufficient clearance burnishes the sidewalls and increases the force required for drawing. Excessive clearance may result in wrinkling of the sidewalls of the drawn shell.

Wrinkling is a wavy condition obtained in deep drawing of sheet metal, in the area of the metal between the edge of the flange and the draw radius. Wrinkling tendency may also be due to material factors such as variations in thickness and anisotropy, or wrinkles may occur if the blankholder pressure is not sufficiently high.

**Radii on Tools.** Tools used for drawing aluminum alloys are ordinarily provided with draw radii equal to four to eight times the stock thickness. A punch nose radius is sometimes as large as ten times the stock thickness.

A die radius that is too large may lead to wrinkling. A punch nose radius that is too sharp increases the probability of fracture or of residual circular shock lines that can be removed only by polishing.

Nonetheless, failure by fracture can sometimes be eliminated by increasing the die radius, or by making the drawing edge an elliptic form instead of a circular arc.

**Surface Finish on Tools.** Draw dies and punches should have a surface finish of 0.4  $\mu\text{m}$  (16  $\mu\text{in.}$ ) or smoother for most applications. A finish of 0.08 to 0.1  $\mu\text{m}$  (3 to 4  $\mu\text{in.}$ ) is often specified on high-production tooling for drawing light-gage or precoated stock. Chromium plating may also be specified to minimize friction and prevent pickup of dirt or other particles that could damage the finish on the part.

**Tool Materials.** The selection of materials for deep-drawing tools is discussed in the article "Selection of Materials for Deep-Drawing Dies" in this Volume. Materials for small dies are chosen almost entirely on the basis of performance, but cost becomes a significant factor for large dies. Local variation in wear on tools is an important factor in tool life. A twentyfold variation in rate of wear can be observed on the die radius.

**Lubricants** for deep drawing of aluminum alloys must allow the blank to slip readily and uniformly between the blankholder and the die and must prevent stretching and galling while this movement takes place.

The drawing compounds can be applied only to the areas that will be subjected to a significant amount of cold working, unless local application interferes with the requirements of high-speed operation. Uniformity of application is critical, especially to enable the maintenance of correct blankholder pressure around the periphery of the die.

**Drawing Limits.** The reduction in diameter that is possible in a single operation with aluminum alloys is approximately the same as that obtainable with drawing-quality steel. For deep-drawn cylindrical shells, reductions in diameter of approximately 40% for the first draw, 20% for the second draw, and 15% for the third and

subsequent draws can be obtained with good practice. The part can usually be completely formed without intermediate annealing. Four or more successive draws without annealing can be performed, with proper die design and effective lubrication, on such alloys as 1100, 3003, and 5005. The amount of reduction decreases in successive draws because of the loss in workability due to strain hardening. The total depth of draw thus obtainable without intermediate annealing exceeds that obtainable from steel, copper, brass, or other common materials.

For high-strength aluminum alloys, the approximate amount of permissible reduction is 30% for the first draw, 15% for the second draw, and 10% for the third draw.

Local or complete annealing is usually necessary after the third draw on alloys such as 2014 and 2024. Alloys 3004, 5052, and 6061 are intermediate in behavior.

The rate of strain hardening is greatest for the high-strength alloys and least for the low-strength alloys. Table 5 shows the changes in mechanical properties that result from successive draws with alloys 3003 and 5052. The major portion of the change is accomplished in the first draw. The rate of strain hardening is more rapid with high-strength heat treatable alloys such as 2014 and 2024.

Practical limits for single-operation deep drawing of cylindrical cups and rectangular boxes have been expressed in terms of dimensional ratios, as shown in Fig. 6. (Reverse redrawing can be used to obtain a deeper shell than indicated by the limits in Fig. 6 for conventional drawing methods.)

The relation of the metal thickness  $t$  to the blank diameter  $D$  is an important factor in determining the percentage reduction for each drawing operation. As this ratio decreases, the probability of wrinkling increases, requiring more blankholding pressure to control metal flow and prevent wrinkles from starting. Figure 7 shows the effect of this ratio on percentage reduction of successive draws, without

**Table 5 Effect of drawing on mechanical properties of aluminum alloys 3003 and 5052**

Number of draws	Tensile strength		Yield strength		Elongation in 50 mm (2 in.), %
	MPa	ksi	MPa	ksi	
Alloy 3003					
0	110	16	41	6	30
1	131	19	117	17	11
2	152	22	145	21	9
3	162	23.5	152	22	8
4	169	24.5	155	22.5	8

1	238	34.5	221	32	6
2	272	39.5	248	36	6
3	296	43	255	37	6
4	303	44	262	38	6
(a)	(290)	(42)	(255)	(37)	(7)

(a) Values in parentheses are typical values for these alloys in the full hard condition.

intermediate annealing, for low-strength alloys such as 3003-O.

**Blank development** is of particular importance in the deep drawing of large rectangular and irregular shapes. Excessive stock at the corners must be avoided, because it hinders the uniform flow of metal under the blankholder and thus leads to wrinkles or fractures.

With suitable tooling and careful blank development, large rectangular and irregular shapes can often be produced economically in large quantities by deep drawing. Smaller quantities are made in sections with inexpensive tooling and then assembled by welding. Both the welding operation and the subsequent grinding and polishing of the weld areas are time-consuming and costly.

**Warping.** The nonuniformity of stress distribution in the drawing of rectangular or irregular shapes increases the tendency toward warping. Bowing or oilcan effects on the major surfaces become more pronounced with increasing size of the part. Changes can sometimes be made in dimensional details of the drawing tools to eliminate these defects without the need for extra forming operations.

**Fig. 6** Drawing limits for single-operation drawing of cylindrical cups or rectangular boxes from aluminum alloy sheet 0.66 to 1.63 mm (0.026 to 0.064 in.) thick. For cylindrical cups, width  $w$  equals diameter, and vertical corner radius  $r$  equals half the diameter. For rectangular boxes, width  $w$  equals the square root of the projected bottom area. If length is more than three times width, drawing limits will be more severe than those shown above. For flanged boxes, the flange width must be included in depth  $h$ .

**Fig. 7** Effect of thickness-to-diameter ratio on percentage of reduction for successive drawing operations without intermediate annealing for low-strength aluminum alloys such as 3003-O.  $t$ , metal thickness;  $D$ , blank diameter

**Miscellaneous Shapes.** Other shapes often produced by deep drawing (besides cylindrical and rectangular shells) include hemispherical shells, flat-bottom hemispherical shells, and tapered shells.

**Hemispherical shells** with a final inside diameter of less than approximately 150 times the original metal thickness can be drawn in one operation. For inside diameters of more than 150 times thickness, two draws are usually required, to avoid wrinkles. Local thinning in the first draw must be avoided if the second draw is to be successful.

**Flat-bottom hemispherical shells**, unless very shallow, require at least two draws. The first draw produces a rounded shape, with a larger radius in the bottom area than on the side areas. The final draw flattens the bottom and gives the sides a uniform curvature of the radius required.

**Tapered shells** require more drawing operations for a given depth of draw than do most other symmetrical shapes. The number of steps required increases with the taper angle.

The bottom edges, except for the final operation, do not have the contour of a circular arc. The profile consists of essentially flat sections at an angle of approximately 40 to 50° from the horizontal. Stepwise reductions are made along the line of final contour, as shown in Fig. 8, and the final draw straightens out the sidewalls to the desired shape.

Each operation after the first is restricted to a shallow draw to minimize strain hardening. With alloys of low and intermediate strength, this procedure makes it possible to complete the

**Fig. 8** Typical progression of shapes in multiple-draw forming of a tapered shell from an aluminum alloy blank 1.63 mm (0.064 in.) thick and 292 mm (11 1/2 in.) in diameter. Dimensions given in inches

series of draws without annealing. Contrary to normal practice, the amount of reduction per draw need not be lowered after the second draw. However, polishing or burnishing is often required on the completed shell to obtain a good-quality finish on the sidewalls.

**Ironing** is avoided in some deep-drawing applications with aluminum alloys but can be used to produce a shell with a heavy bottom and thin sidewalls. The shell is first drawn to approximately the final diameter. The drawing lubricant is then removed, and the shell is annealed, bringing it to temperature rapidly to minimize the formation of coarse grains in areas that have been only slightly cold worked.

The sidewalls can then be reduced in thickness by 30 to 40% in an ironing operation. By repeating the cleaning, annealing, and ironing steps, an additional reduction of 20 to 25% can be obtained, with good control over wall thickness.

A typical use of ironing is shown in Fig. 9. Here, a cylindrical shell is produced with a thick bottom and thin sidewalls by a single deep draw and two successive ironing operations. The approximate final diameter and approximately half the final depth are obtained in the drawing operation. Wall thickness is reduced 33% in the first ironing step and 19% in the second.

**Hot Drawing.** Severe drawing operations are often impossible to perform at room temperature on large and relatively thick shapes made from high-strength aluminum alloys. However, the lower strength and increased ductility at temperatures above the recrystallization point of the alloy make it possible to produce large and relatively thick shapes by hot drawing. There is little or no advantage when stock is less than 3.2 mm (0.125 in.) thick. Alloys frequently used in applications of this type include non-heat-treatable alloys 5083, 5086, and 5456, and heat treatable alloys 2024, 2219, 6061, 7075, and 7178.

Heavy-duty presses and related equipment are required. Drawing temperatures range from 175

**Fig. 9** Progression of shapes in production of a shell with a thick bottom and thin sides in one draw and two ironing operations. Dimensions given in inches

to 315 °C (350 to 600 °F). The length of time the workpiece is held at temperature is controlled to avoid excessive grain growth in areas with little strain hardening. Ordinary drawing compounds break down or burn at elevated temperature and are not suitable for hot drawing operations.

Graphite-containing tallow and hard yellow naphtha soap have sometimes been used as lubricants at intermediate elevated temperature. Lubricants that remain stable above 260 °C (500 °F) include graphite and molybdenum disulfide. These materials can be used in the colloidal form with a volatile vehicle, mixed with other lubricants, or applied to the die as powders.

## Spinning

Spinning is often used for the forming of aluminum alloy shapes that are surfaces of revolutions. The manual lathes, automatic spinning machines, chucks, and tools used for aluminum alloys are essentially the same as those used for steel and the other metals commonly formed by spinning (see the article "Spinning" in this Volume).

Hand-spinning lathes and simple tools are suitable for forming aluminum alloy blanks 0.51 to 2.05 mm (0.020 to 0.081 in.) thick; with proper care, stock as thin as 0.10 mm (0.004 in.) can be spun. For thicker and larger blanks, auxiliary equipment is used to apply pressure to the workpiece. This equipment varies from a simple scissors arrangement to feed screws for controlling tool advance; pressure against the work is provided by air or hydraulic cylinders.

Blanks up to 6.4 mm (1/4 in.) thick can usually be spun at room temperature. For greater thicknesses, semimechanical to fully mechanical equipment is used, and the work metal is heated. Work metal 25 mm (1 in.) or more in thickness requires special heavy-duty machines and hot spinning.

Aluminum alloy parts 75 mm (3 in.) thick have been spun experimentally. Equipment is available for the spinning of parts as large as 5 m (16 ft) in diameter.

Tolerances for the spinning of aluminum alloys are essentially the same as those for other common metals.

**Alloys.** A number of aluminum alloys are widely used in spinning applications. Desirable properties are ductility, relatively low ratio of yield strength to ultimate strength, low rate of work hardening, and small grain size.

The alloys of low and intermediate strength that are spun most frequently include 1100, 2219, 3003, 3004, 5052, 5086, and 5154. Annealed blanks are generally used for severe forming; however, a harder temper is sometimes preferred, if it is sufficiently formable, to avoid a tendency to ball up ahead of the tool. A harder temper also may be used when forming is not severe enough to give the product its necessary strength by work hardening.

Heat treatable alloys used for high strength in the finished part are 2014, 2024, and 6061. If the forming is extensive, these alloys often must be annealed several times during spinning, or they may be spun hot.

One method used frequently for spinning heat treatable alloys is:

- Spin annealed blank to approximate form
- Solution heat treat and quench
- Spin to final form at once, before appreciable age hardening

If spinning to the final form cannot be done after solution heat treating and quenching, the quenched parts should be placed in a refrigerator, or packed in dry ice, and held as close to -20 °C (0 °F) as possible until they can be spun. The parts are aged to the T6 temper after spinning has been completed.

**Typical spindle speeds** for spinning flat blanks and drawn shells of various diameters are listed in Table 6. Rotational speed is decreased as blank diameter increases, so that peripheral speed is maintained in the same range regardless of the size of the workpiece. Peripheral speed ordinarily averages approximately 915 m/min (3000 ft/min) for aluminum alloys. This is somewhat faster than the speeds normally used in spinning copper, brass, stainless steel, and low-carbon steel.

**Lubricants** are needed in nearly all spinning operations. Beeswax, tallow, and petroleum jelly are suitable for most small parts. Hard yellow naphtha soap is an effective lubricant for larger workpieces. Colloidal graphite in kerosene, or compounds containing molybdenum disulfide, are used in hot spinning. Lubricating compounds used must be easily removable from the finished part without costly treatments.

**Applications.** Parts produced from aluminum alloys by spinning include tumblers, pitchers, bowls, cooking utensils, ring molds, milk cans, processing kettles, reflectors, aircraft and aerospace parts, architectural sections, tank heads, and streetlight standards.

**Table 6 Typical spindle speeds for the spinning of aluminum alloy flat blanks**

Blank diameter		Spindle speed, rpm
m	in.	
Flat blanks		
Up to 0.3	Up to 12	600–1100
0.3–0.6	12–24	400–700
0.6–0.9	24–36	250–550
0.9–1.8	36–72	50–250
1.8–3.0	72–120	25–50
3.0–4.5	120–180	12–25
4.5–5.3	180–210	12
Drawn shells		
0.25–0.35	10–14	1000–1200
0.35–0.50	14–20	650–800
0.50–0.75	20–30	475–550
0.75–1.0	30–40	325–375
1.0–1.3	40–50	250–300
1.3–1.8	50–70	200–210
1.8–2.3	70–90	150–175

Spinning is often selected in preference to drawing when quick delivery of small quantities is important, because the spun parts can usually be delivered before drawing tools have been made. Cones, hemispheres, tapered shapes, and parts with complex or reentrant contours (if surfaces of revolution) are often more readily formed by spinning than by other methods. Spinning is also used for very large parts when suitable press equipment and tools are not readily available or are too costly.

Spinning is not usually economical for quantities of more than 5000 to 10,000 pieces because of comparatively low production rates and resulting high unit labor costs. There are exceptions, especially in the power spinning of truncated cone-shaped parts having included angles of 40° or more. Spinning is capable of producing such parts at lower cost than deep drawing, it gives a uniform wall thickness and a surface free from wrinkles, and it increases the tensile strength of the work metal by as much as 100%.

## Stretch Forming

Almost all of the aluminum alloys can be shaped by stretch forming. In this process, the work metal is stretched over a form and stressed beyond its yield point to produce the desired contour (for a detailed description, see the article "Stretch Forming" in this Volume).

Typical shapes produced by stretch forming are shown in Fig. 10. These include large shapes with compound curvature formed by longitudinal and transverse stretching of sheet, and compound bends or long, sweeping bends formed from extrusions.

Stretch forming is normally restricted to relatively large parts with large radii of curvature and shallow depth, such as contoured skin. The advantage is uniform contoured parts at faster speed than can be obtained by hand forming with

**Fig. 10** Typical stretch-formed shapes. (a) Longitudinal stretching. (b) Transverse stretching. (c) Compound bend from extrusion. (d) Long, sweeping bend from extrusion. Dimensions given in inches

a yoder hammer or other means. Also, the condition of the material is more uniform than that obtained by hand forming. The disadvantage is the high cost of initial equipment.

Material used for stretch forming should be limited to alloys with fairly high elongation and good spread between yield and tensile strength. Most of the common alloys are formed in the annealed condition. It is possible to stretch form the heat treatable alloys in tempers T4 or T6, where the shape is not too deep or where narrow width material is used. For the deeper curved shapes, the material is formed in the annealed O temper, heat treated, and reformed, to eliminate distortion resulting from heat treatment. As previously stated, the material should be reformed as fast as possible after heat treatment. In some instances, the material is formed immediately after heat treating and quenching.

**Alloys.** Properties desirable for stretch forming are high elongation, wide forming range (spread between yield strength and tensile strength), toughness, and fine grain structure. Table 7 shows the effect of elongation and forming range on stretchability ratings for the alloys most commonly used in stretch forming. The stretchability rating varies directly with the forming range, except for 6061-W (which has somewhat higher elongation than adjacent alloys) and 7075-T6 (which has by far the lowest elongation listed). Alloys 1100-O and 3003-O, with the highest elongation shown, nevertheless are less desirable for stretch forming than are the alloys above them in the list. Their low strength and the narrow spread between yield strength and tensile strength make them particularly susceptible to local necking and premature failure in stretch forming.

**Tools.** The materials used for the form block or die depend on the production quantities required, the severity of local stress and wear on the die, and the thickness and wear properties of the alloy to be formed. Materials include wood, plastics, faced concrete, cast zinc alloys, aluminum tool and jig plate, cast iron, and (rarely) steel or chromium-plated steel.

**Lubricants** are recommended in the stretch forming of aluminum alloys. Water-soluble oils are commonly used, with viscosity dependent on

the severity of forming. Calcium-base greases, paraffin, beeswax, and commercial waxes also are used. The application of too much lubricant can result in buckling of the workpiece.

Sometimes, a layer of sheet rubber, glass cloth, or plastic between die and workpiece serves as a lubricant. Because of their inherent lubricity, zinc alloy dies require only a minimum of lubrication. Smooth-surface plastic dies may require no lubrication, because of their low coefficient of friction against aluminum.

**Applications.** The various stretch-forming techniques (including stretch drawing, stretch wrapping, and compression and radial drawing) are used extensively in the aerospace industry. Typical parts produced include wing-skin and fuselage panels, engine cowlings, window and door frames, and trim panels used in aerospace, automotive, architectural, and appliance industries.

*Stretch draw forming* of aluminum is done using both the matched-die and form block techniques. The matched-die method uses a single-action hydraulic press equipped with a means of closing and moving the jaws that grip each end of the blank. The punch is attached to the bed of the press, and the die is attached to the ram.

The alternate method uses a form block that is attached to a stationary bed or a hydraulic cylinder. With this method, the blank is gripped with jaws that hold it in tension or draw it over the form block.

*Stretch wrapping* uses a form block that is bolted to a rotary table. One end of the blank is clamped to the form block or to a table-mounted gripper. A hydraulic cylinder or a gripper applies tension to the other end of the blank while the form block revolves into it with the turning of the table.

Shaped form blocks that match the contour of extruded or rolled sections are used for support during forming. Filler strips, either segmented or made of low-melting alloys or strips of aluminum, are used to prevent the collapse of sections.

*Radial draw forming* is a combination of stretch wrapping and compression forming. The workpiece is pressed against the form block by a roller or shoe while being wrapped around the

turning form block. This method can be used, for example, to form a flange to a compound curvature while forming a leg, as in the part shown in Fig. 11.

## Rubber-Pad Forming

Aluminum alloys are formed by several techniques that can be classified as rubber-pad forming. A general description of processes, equipment, tools, and applications is given in the article "Rubber-Pad Forming and Hydroforming" in this Volume.

**Alloys** for rubber-pad forming are selected on the same basis as they are selected for similar bending or deep-drawing operations. With non-heat-treatable aluminum alloys, the temper that will meet the forming requirements and give the maximum strength in unworked areas is usually chosen.

Heat treatable aluminum alloys ordinarily are either formed in the annealed temper and then solution heat treated or formed in the freshly quenched W temper.

**Tool materials** are usually masonite for short runs, and aluminum alloy, zinc alloy, or steel for longer runs. Several types of rubber have been used as the pad material. Certain grades of rubber have particularly good resistance to oils and forming lubricants and are available in a range of hardness, tensile strength, and deflection characteristics to meet different forming requirements.

**Capabilities.** A given alloy and temper can sometimes be formed more severely by rubber-pad forming than with conventional tools because of the multidirectional nature of the force exerted against the workpiece. Also, the variable radius of the forming pad assists in producing a more uniform elongation of the workpiece than in conventional forming operations.

Forming the shallow part shown in Fig. 12 with a rubber pad and a rigid female die used the variable radius to advantage. The development of wrinkles was almost eliminated, because the rubber acted as a blankholder and kept the work in contact with the flat and contoured die surfaces

**Table 7 Mechanical properties and stretchability ratings for aluminum alloys most commonly used in stretch forming**

Alloy	Tensile strength		Yield strength		Forming range(a)		Elongation in 50 mm (2 in.), %	Stretchability rating(b)
	MPa	ksi	MPa	ksi	MPa	ksi		
7075-W(c)	331	48	138	20	193	28	19	100

**Fig. 11** Aluminum alloy 7075-O radial draw formed T-section with radical changes in angle between leg and flange. Dimensions given in inches

**Fig. 12** Shallow part that was drawn from aluminum alloy 6061-O with a rubber pad and a rigid female steel die, in one operation. Dimensions given in inches

as the drawing progressed. A drawing compound was used on the blank.

**Limitations.** The simpler types of rubber-pad forming have relatively low production rates and correspondingly high unit labor costs compared with punch-press operations. However, the hydroforming (fluid forming) process is adaptable to automatic loading equipment and thus has fairly high production rates.

**Applications.** Rubber-pad forming is widely used in the aerospace industry, especially for structural parts and skin components. Products made in other industries include appliance parts, license plates, numerals, lighting reflectors, skin panels for buildings, moldings, utensils, and parts drawn from prefinished sheet.

Most rubber-pad forming is done on material 1.6 mm ( $1/16$  in.) or less in thickness, with only a small percentage being thicker than 6.4 mm ( $1/4$  in.). However, aluminum alloy parts 15.8 mm ( $5/8$  in.) thick have been formed in special heavy-duty equipment of the rubber-diaphragm type.

Some bulkheads and brackets have both straight and curved flanges with joggles at both ends. The form blocks for such parts are sometimes interchangeable between the Guerin and Verson-Wheelon rubber-pad processes (see the article "Rubber-Pad Forming and Hydroforming" in this Volume). Handwork is usually necessary to set the joggles and to smooth minor buckling in the shrink flanges.

The simultaneous blanking and piercing of flat stock can also be done with rubber-pad tooling. This type of operation is limited to aluminum alloy sheet no thicker than approximately 1.63 mm (0.064 in.).

The control of metal movement that can be obtained with rubber-pad forming not only permits more severe forming than do conventional tools but also is applicable to beading operations. Beads are frequently used to obtain rigidity on large surfaces without increasing the metal thickness.

With a conventional steel punch, die, and blankholder, metal is moved from the edges of the workpiece toward the bead, making the edges somewhat concave and sometimes producing warpage or oilcan effects. Some movement of metal toward the formed area is usually desirable, in order to prevent excessive thinning or cracking of the beads. In the forming of some parts, however, it may be necessary to restrict

metal movement to the immediate vicinity of the beads.

The deep-drawing capabilities of rubber-pad processes vary with the different types of equipment. The severity of drawing possible with heavy-duty rubber-pad drawing by the Marform process (see the article "Rubber-Pad Forming and Hydroforming" in this Volume) is compared as follows with that possible in conventional drawing. The comparison is based on the drawing of alloys 1100-O and 3003-O:

Drawing severity	Reduction in diameter, %	Ratio of depth to diameter
<b>Rubber-pad drawing</b>		
Typical	57	1.1
Maximum	72	3.0
<b>Conventional drawing</b>		
Maximum	40	0.45

## Warm Forming of Aluminum

Warm forming is a method for improving the formability of aluminum. Interest in warm forming of lightweight materials began in the 1970s, when it was discovered that an aluminum alloy with 6% Mg content could give a 300% total elongation at approximately 250 °C (480 °F) (Ref 18).

In warm forming of aluminum, the die and the blankholder usually are heated to a temperature in the range of 200 to 300 °C (390 to 570 °F). Many studies show a significant increase in formability of 5xxx and 6xxx series when warm forming is used.

The dies and blankholder are heated with electrical heating rods that are located in the dies. It is necessary to heat up the corners of the dies, because the corners are critical in controlling the metal flow. So, in most cases, it is not necessary to heat up the entire die. Straight sides can be cooled by using water or oil. This reduces material flow, similar to the effect of a draw bead.

Many studies have been conducted in warm forming of aluminum alloys. For example, experimental analyses of rectangular conical cups from an aluminum alloy (5754-O) drawn at room temperature (20, 100, 175, and 250 °C, or 70, 212, 350, and 480 °F) were conducted (Ref 19). Maximum cup heights, obtained without fracture, were compared. These cup heights were 35, 38, 38, and 60 mm (1.4, 1.5, 1.5, and 2.4 in.) for temperatures of 20, 100, 175, and 250 °C (70, 212, 350, and 480 °F), respectively (Ref 19).

Uniaxial tensile deformation and biaxial forming behavior of three aluminum sheet alloys, 5182 + 1% Mn, 5754, and 6111-T4, were studied in the warm forming temperature range of 200 to 350 °C (390 to 660 °F) and in the strain rate range of 0.015 to 1.5 s<sup>-1</sup> (Ref 20). Attempts have been made to process the selected aluminum sheet alloys so that the microstructural change during warm forming provides adequate recovery favorable to formability but does not

deteriorate the postforming properties. The total elongation in uniaxial tension was found to increase with increasing temperature and to decrease with increasing strain rate. The enhanced ductility at elevated temperatures is contributed primarily from the postuniform elongation that becomes dominant at elevated temperatures and/or slow strain rates. The results of the biaxial forming tests also indicate that, as temperature is increased, part depth, stretchability, and limiting strain level before failure are all increased. The enhancement of strain-rate sensitivity (*m*-value) with increasing temperature accounts for the plasticity improvement at elevated temperatures under both the uniaxial tension and the biaxial forming conditions. The uniaxial tensile test was identified to serve as a screening test for ranking relative formability among different sheet alloys. The strain-hardened 5xxx alloys (5182 + Mn and 5754) have shown better formabilities than the precipitation-hardened alloy (6111-T4). Furthermore, warm forming limits for the aluminum alloys are superior to those for aluminum-killed steels at room temperature.

## Superplastic Forming (Ref 21)

Superplastic behavior has been demonstrated in several aluminum alloys, including the high-strength alloy 7475. The prime material requirement for superplasticity—a fine, stable grain size—can be achieved in aluminum alloys by either static or dynamic recrystallization. In static recrystallization, a deformed microstructure is allowed to undergo discontinuous recrystallization during static annealing, leading to a fine-grain microstructure at the start of superplastic forming.

In dynamic recrystallization, a deformed microstructure undergoes gradual, continuous recrystallization and grain refinement in the course of superplastic forming.

The microstructures of superplastic aluminum alloys can be either dual-phase or essentially a single phase with very small amounts of second phase present. Some amount of second phase is always necessary to develop and stabilize a fine-grain structure.

Table 8 lists the nominal compositions of several superplastic aluminum alloys, their typical grain sizes, and selected mechanical properties. For comparison, the elongations and yield strengths of aluminum alloys 1100-O and 2024-T3 are also shown.

### Superplasticity in Aluminum Alloy 7475.

The high strength and high fracture toughness of alloy 7475 are the main reasons for examining superplasticity in this material. A number of grain refinement methods have been developed for 7xxx-series aluminum alloys; of these, the Rockwell method (Ref 30) has been relatively easy to implement. A schematic of the Rockwell grain refinement process is shown in Fig. 13. A critical aspect of the process is the heating rate in recrystallization, which must be extremely rapid

in order to activate simultaneously as many nuclei as possible.

Stress versus strain-rate plots and corresponding values of strain-rate sensitivity index  $m$  for alloy 7475 are shown in Fig. 14. The effect of grain size on flow stress and  $m$  value is apparent: Flow stress increases with grain size, while  $m$  decreases. At a grain size of 10 to 14  $\mu\text{m}$  (400 to 560  $\mu\text{in.}$ ) and a strain rate of  $2 \times 10^{-4} \text{ s}^{-1}$ , flow stresses are very low ( $\sim 690 \text{ kPa}$ , or 100 psi). Peak  $m$  values are very high ( $\sim 0.8$ ). Flow stress at the same strain rate but a grain size of 40  $\mu\text{m}$  (1600  $\mu\text{in.}$ ) is more than doubled to approximately 1380 kPa (200 psi); peak  $m$  value has decreased to approximately 0.7.

**Superplastic Forming Processes.** A number of processes are used for superplastic forming,

including blow forming, vacuum forming, thermoforming, deep drawing, and dieless drawing. All of these processes are discussed in detail in the article "Superplastic Sheet Forming" in this Volume. Information on superplastic forming of titanium alloys also is discussed in the article "Forming of Titanium and Titanium Alloys" in this Volume.

**Cavitation** (formation of internal microvoids during superplastic forming) is a problem in most superplastic aluminum alloys. Many factors, including alloy cleanliness, grain size, flow stress, strain rate, forming temperature, and hydrostatic pressure, influence cavitation in aluminum alloys. Factors that increase the creep-flow stress of the alloy increase the tendency toward cavitation. Creep-flow stress increases

with high applied strain rate, low forming temperature, or with large grain size or excessive grain growth (when above the homologous temperature for creep deformation).

Cavitation can be reduced by imposing a pressure on the back side of the sheet during forming (Fig. 15). The forming pressure must be higher than this back pressure. The same forming rates can be achieved with or without back pressure. Back pressures of 690 to 3450 kPa (100 to 500 psi) are generally suitable for suppressing cavitation. A die apparatus used to provide back pressure during forming is illustrated in Fig. 15.

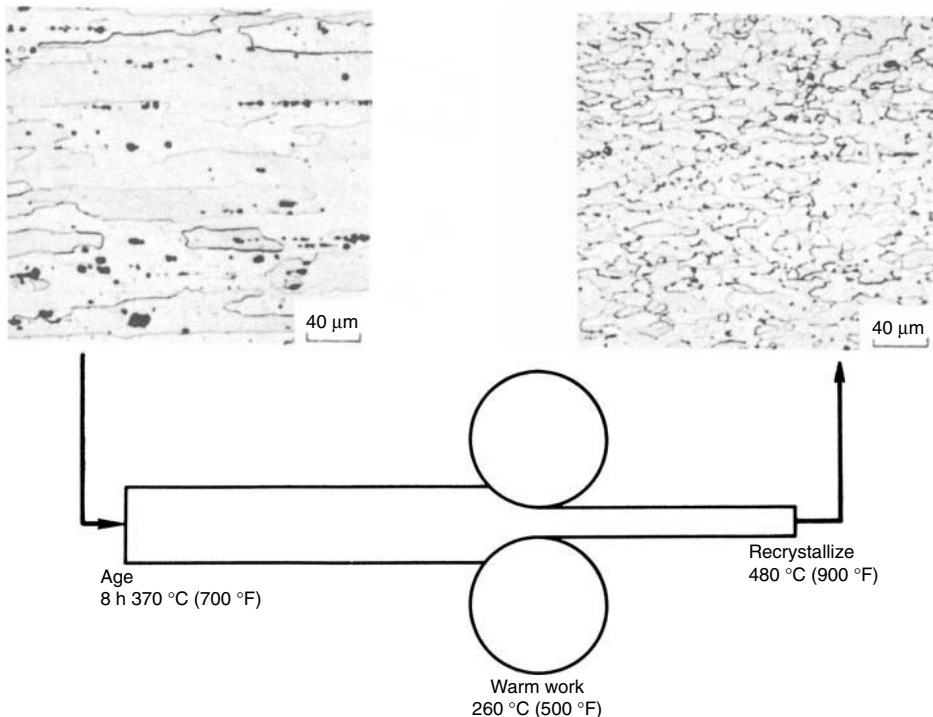

**Applications.** The use of superplastically formed aluminum components in the aircraft industry is increasing (Ref 31). Figure 16 illustrates the cost and weight savings possible when conventionally fabricated components (in this case, an airframe member) are replaced by superplastically formed parts.

**Table 8 Nominal compositions, typical grain sizes, and selected mechanical properties of several superplastic aluminum alloys**

Elongation and yield strength of aluminum alloys 2024-T3 and 1100-O are shown for comparison.

## Explosive Forming

Explosive forming is one of the high-energy-rate forming methods that are employed in the production of aluminum alloy parts, mainly in the aerospace industries. It is often used to produce parts whose size exceeds the limits of conventional equipment or whose thickness requires pressures not obtainable with conventional equipment. It is also used to form small quantities of complex parts that would be more costly to produce by conventional techniques.

Deformation velocities are several hundred feet per second, compared with 0.15 to approximately 6 m/s (0.5 to approximately 20 ft/s) for conventional forming processes. The time required for the workpiece to deform to its final shape is a few milliseconds, with working pressures of several thousand to several hundred thousand pounds per square inch. Water usually serves as the pressure medium.

Details of equipment, tools, and procedures used in explosive forming are available in the article "High-Velocity Metal Forming" in this Volume.

**Capabilities.** Types of operations possible in explosive forming include panel forming (bending), piercing, flanging, shallow dishing, deep drawing, and cylindrical bulging. Part dimensions range from 25 mm (1 in.) to approximately 15 m (50 ft); work metal thicknesses range from several thousandths of an inch to approximately 152 mm (6 in.).

**Alloys.** The explosive forming process can be used with any aluminum alloy. Formability may be roughly compared in terms of the ordinary tensile elongation values, but the function is different for each alloy, because of different strain-rate behavior. Alloy 1100-O is rated the most formable of all common metals by explosive forming.

**Effect on Mechanical Properties.** Changes in mechanical properties as a result of explosive free-forming operations are essentially the same as those observed with conventional forming techniques to produce the same part. Explosive

forming in a die, however, often causes the metal to strike the die at extremely high velocity. The resulting high interface pressures can increase the yield and tensile strengths substantially. Forming capability is increased when critical forming velocities are exceeded.

**Dies.** Only a forming die or cavity is needed for explosive forming, because the shock wave acts as a punch. Some direction and concentration of the shock wave is obtained with suitably shaped and positioned reflectors.

Cast iron and cast steel are the most frequently used die materials. A variety of other materials and combinations of materials are used, depending on the impact of the shock wave workpiece against the die, the size of the die, dimensional tolerances on the part, and quantity of parts. These materials include low-melting cast alloys and plastics, reinforced concrete, concrete faced with plastic-glass composites, and high-impact steel.

The air between the workpiece and die cavity must be evacuated before forming, because the forming speed is so great that the air will be trapped between the workpiece and die rather than displaced, as in conventional press forming. Trapped air and excessive lubrication cause malformed areas. The vent holes for evacuating the air must be placed in noncritical areas; otherwise, marks will appear on the formed parts. In thinner parts, the forming force will pierce holes in the parts, with the vent hole acting as a piercing die. The surface finish of the die cavity is also important because it is reproduced in mirror image on the workpiece.

**Lubricants,** if used, are usually extreme-pressure types. Because of the high velocity and the extreme pressures of forming, excessive lubrication must be avoided. Dies of low-melting alloys or those with smooth surfaces require little or no lubrication.

**Springback** is of importance in die design. Increasing the explosive charge or reducing the standoff distance reduces springback. However, die wear is thereby increased, and the more brittle die materials may fracture. A compromise is often required. Compensation is sometimes made for die wear by reducing charge size or increasing standoff distance to produce a controlled amount of springback and maintain dimensional tolerances.

Studies on alloy 2219 have shown springback to increase when sheet thickness decreases between 6.35 and 0.81 mm (0.250 and

0.032 in.), and also to increase substantially when a lubricant is applied. Incremental forming, on the other hand, has been observed to reduce the extent of springback. Draw radius, draw depth, and die material have shown no significant effect on springback behavior.

**Examples of Applications.** The forming of flat and moderately curved shapes has been one of the most useful applications of explosive forming. These have included parts ranging from small, detailed items a few square inches in area to large panels with areas in excess of 2.8 m<sup>2</sup> (30 ft<sup>2</sup>).

The curved, corrugated panel shown in Fig. 17 was formed from alloy 2014 in the O, T4, and T6 tempers in a laminated epoxy-fiberglass die. The panel was formed in a single shot, using a detonating fuse as a source of energy.

Another example of an explosively formed aluminum part is the alloy 6061 instrument container shown in Fig. 18. The part was produced in a closed die using a hydraulic clamping system; tolerances were  $\pm 0.076$  mm (0.003 in.).

Tubular parts also are readily shaped by explosive forming, using a length of detonating cord suspended along the axis of the tube.

## Electrohydraulic Forming

Another high-energy-rate forming (HERF) method used in the fabrication of aluminum alloy parts is electrohydraulic forming (EHF). In this process, either a spark gap or an exploding bridgewire is employed to discharge

**Fig. 16** Example of cost and weight savings obtainable using superplastic forming in the aircraft industry. Conventionally fabricated part (a) had 15 parts and required 212 fasteners; the superplastically formed part (b) consists of 3 parts and requires 45 fasteners. This results in a 56% cost savings and a 13% weight savings.

**Fig. 17** Curved, corrugated panel produced by explosive forming from aluminum alloy 2014 0.51 mm (0.020 in.) thick. Dimensions given in inches

**Fig. 18** Aluminum alloy 6061 instrument container fabricated from a blank by explosive forming. Courtesy of Explosive Fabricators, Inc.

electrical energy in water or another liquid. This generates an extremely high pressure and a shock wave similar to those produced in explosive forming.

Once the energy is released in the transfer medium, the remainder of the operation is essentially the same as it is for explosive forming.

**Capabilities** of EHF differ somewhat from those of explosive forming. The spark-gap method can apply programmed repetitive shock waves of varying magnitude without removal of the workpiece from the die.

The exploding-bridgewire method is less readily automated, but the shock wave can be localized and directed by the shape and placement of the wire.

Dimensional tolerances can be held to lower limits than with explosive forming, because the discharge of energy is more closely controlled. For this reason, EHF is sometimes used for a restrike or sizing operation after preliminary explosive forming to an approximate contour.

Commercial equipment is available that can produce approximately 3000 small- or medium-sized pieces per week.

**Examples of Applications.** Electrohydraulic forming is well suited to the production of parts such as those shown in Fig. 19 and to the production of other transitional shapes in tubing. Both of the parts shown in Fig. 19 were originally fabricated by welding two drawn pieces, but the

use of EHF resulted in considerable cost savings as well as in parts with closer tolerances and better surface finish.

## Electromagnetic Forming

Operations generally similar to those described for the preceding two HERF methods also can be carried out by electromagnetic forming (EMF). In this process, the discharge of a capacitor through a coil generates an intense magnetic field. This field interacts with the electric currents induced in a conductive workpiece to produce a force perpendicular to the workpiece surface.

Details of the process and of equipment, tools, and procedures are described in the article "High-Velocity Metal Forming" in this Volume. The method is suitable for aluminum alloys because of their formability and high electrical conductivity. Pressure-tight joints, electrically or thermally conductive joints, torque joints, and structural joints between metals can be produced by EMF techniques in a variety of shapes.

**Examples of Applications.** Electromagnetic forming is being used to attach an aluminum skirt to a machined bulkhead as part of an engine inlet mounting assembly for an aircraft (Fig. 20). The skirt is positioned over the bulkhead, and EMF is used to compress the skirt locally into a pre-machined configuration in the bulkhead.

**Fig. 19** Alloy 5052-O stepped tube and offset tube produced as one-piece units by electrohydraulic forming. The parts were originally produced as welded assemblies. Dimensions given in inches

**Fig. 20** Aluminum alloy engine inlet mounting assembly for an aircraft before (right) and after (left) assembly by electromagnetic forming. Courtesy of Grumman Aircraft Systems

**Fig. 21** Schematic of aluminum alloy 6063-T832 drive shaft with ends attached to drawn aluminum shaft by electromagnetic forming (EMF). Source: Ref 32

Welding and mechanical fasteners also were considered for this application. Welding was eliminated because of the large difference in section thicknesses being joined and the distortion that would accompany the welding operation. Mechanical fasteners were eliminated because of the increased stresses that would be caused by adding holes to the bulkhead. Joint integrity is of paramount importance because the completed assembly is used in the very front of an aircraft engine, and any failure could result in ingestion of debris into the engine itself. The EMF joint meets all design requirements for the application. Another example of the use of EMF is in the joining of both ends to a tubular aluminum alloy 6063-T832 drive shaft (Fig. 21).

## Hydraulic Forming

True hydraulic forming by direct oil pressure against the surface of the workpiece has been applied to aluminum alloy flat stock. The process has been used mainly for the drawing of multiple beads on small quantities of large, flat sheets of thin material for aerospace applications. As shown in Fig. 22, a form block attached to the ram of the press holds the workpiece tightly against a selector plate, through which oil is introduced into channels at the bead locations.

In typical applications, up to 20 beads have been drawn in parts 510 to 760 mm (20 to 30 in.) wide by 1525 to 2030 mm (60 to 80 in.) long and approximately 0.30 mm (0.012 in.) thick, made from alloy 2024. Clamping force required is approximately 2.7 MN (300 tonf), and necessary forming oil pressure is approximately 6.9 MPa (1 ksi). Vents are provided in the form block to allow the escape of air from each bead cavity. The oil film left on the form block after each operation provides sufficient lubrication to draw the next part.

## Forming by Shot Peening

The major application of shot peening is to increase the fatigue life of metal parts by producing a uniform compressive stress in the surface layers. Shot peening is sometimes used as a metal-forming process and is especially useful in the forming of large, irregularly shaped parts from aluminum alloy sheet stock.

**Shot.** When steel shot is used topeen form aluminum alloy parts, the parts are usually treated chemically after forming to remove

**Fig. 22** Typical tooling setup for hydraulic forming of multiple beads in flat stock

particles of iron or iron oxides that may be embedded in the surface.

Slugs cut from stainless steel or aluminum alloy wire are sometimes used. When peening with aluminum alloy slugs, no subsequent chemical treatment is needed, and the danger of overpeening and high localized residual stress (which sometimes occurs with steel or iron shot) is also eliminated.

Automatic or semiautomatic devices are available for the separation and removal of fines and undersized shot, and for the addition of new shot. Manual handling of shot and batch replacement may be more feasible for small-scale operations. The proportion of full-sized shot in the system is usually maintained at a minimum of 85%.

**Control.** The effectiveness of shot peening depends on the size, shape, material, and velocity of the shot, and on the quantity of shot striking a unit area per unit time. The combined effect of these variables is known as peening intensity.

The angle at which the shot strikes the work also affects the peening intensity, which is proportional to the sine of the angle of impingement. The amount of breakdown of the shot will, of course, also affect peening intensity. The extent of surface coverage as measured by visual or instrumental techniques is often used, together with Almen test strips, to control peening operations.

**Applications.** One of the earliest forming applications of shot peening was the contour forming of integrally stiffened aircraft wing panels. Because of their extreme length and variable thickness, these parts are ill suited for forming by mechanical processes. Other parts formed by shot peening include honeycomb panels and large tubular shapes. Large, irregularly shaped parts are conveniently formed by this method.

If a part is deformed beyond the specified amount, the contour can be corrected by peening the reverse side. Also, peening can be used as a salvage procedure to correct the contours of bent or distorted parts.

The process is usually carried out as a free-forming technique, without dies or form blocks. Contour is checked against a template. The peening intensities and the number of passes are varied depending on the material and the severity of forming required. Local areas can be subjected to the required treatment.

## Drop Hammer Forming

Drop hammer forming is of value for limited production runs that do not warrant expensive tooling. For example, it is often used in experimental work to make trial parts and parts that are expected to undergo frequent design changes.

Tooling costs are low, and finished parts can be produced quickly. However, only relatively shallow parts with liberal radii can be drop hammer formed, and material thickness must be

in the range of approximately 0.61 to 1.63 mm (0.024 to 0.064 in.). Also, wrinkling occurs frequently, and a high degree of operator skill is required.

**Equipment and Tools.** Air-operated hammers with sensitive and accurate control are usually preferred to hammers operated by gravity or steam.

The material is formed in a sequence of small steps. In a typical setup, several plywood or rubber spacers are stacked on the die face, and one or more are removed after each stroke to form the workpiece progressively.

In a variation of this procedure, a series of dies can be used to accomplish the progressive forming. Only the last of these dies requires close tolerances. A rubber pad several inches thick is sometimes used between workpiece and punch in all but the final step.

Dies are simple and inexpensive. Bottom dies are cast from zinc alloy. Punches can also be made from zinc alloy, but if requirements on sharpness of radii and accuracy of contour are not stringent, punches cast from lead are used for short runs. These need not be cast accurately because they deform to the shape of the bottom die in a few strokes. For longer runs, tools can be made of cast iron or cast steel. Lubrication requirements are similar to those for drawing operations.

**Alloys** used most frequently are 1100, 3003, 2024, 5052, 6061, and 7075. Annealed tempers permit the greatest severity of forming. Intermediate tempers of the non-heat-treatable alloys are often used for channel shapes and shallow, embossed panels. Heat treatable alloys can be partly formed in the annealed condition and given a restrike operation after heat treatment, or they can be formed in the fresh W temper.

All processing conditions being equal, aluminum alloy stock will wrinkle more readily than the same thickness of steel sheet. For comparable results in forming, aluminum alloys must be approximately 40% thicker than steel. More information on this process is available in the article "Drop Hammer Forming" in this Volume.

## Other Forming Methods

A number of additional conventional forming processes are applied to aluminum alloy sheet, including embossing, coining, stamping, curling, expanding or bulging, contracting or necking, hole flanging, and beading or ribbing.

**Embossing, Coining, and Stamping.** These three closely related methods for making shallow impressions and patterns by compression between a punch and a die are frequently combined with drawing. In these operations, the material must yield under impact and compression, and it must be ductile to avoid fracture in tension.

Uniform thickness in all areas of the workpiece generally is maintained in embossing; however, some stretching occurs. Simple designs are produced with light pressure, using a punch

of the desired shape and an open female die. Complex patterns require high pressure and a closed matching female die or a rubber female die.

Coining differs from embossing in that the metal is made to flow, thus producing local differences in metal thickness. The design on the top and bottom surfaces may be different. Very high pressure is required.

Stamping produces cut lines of lettering or patterns in one side of the workpiece, to a depth of 0.51 to 1.0 mm (0.020 to 0.040 in.). The depth of penetration must be carefully controlled to minimize distortion and to prevent the design from appearing on the opposite side. Outline or open-face stamps are preferred.

**Curling** or false wiring can be done in a variety of machines, such as press brakes, single-action punch presses, lathes, roll-forming machines, or special beading machines. The selection of machine depends on the shape and the number of parts required. Circular parts are usually curled on spinning lathes, and rectangular parts are curled in presses. Long, relatively narrow parts can be curled in press brakes or roll-forming machines. Various types of machines have been built specifically for curling in high production quantities.

The edge to be curled should be of uniform height and free from roughness on the outside of the curl. Preferably, it should be rounded slightly before beginning the operation. The minimum radius for curling should be  $1\frac{1}{2}$  to 4 times the metal thickness, depending on alloy and temper.

**Expanding or bulging** of aluminum alloy parts can be carried out by several means, including segmented mechanical dies, rubber punches, or hydraulic pressure.

Segmented mechanical expanding dies are relatively inexpensive and are capable of high production rates but are limited to certain shapes and may produce marks on thin stock or low-strength alloys.

Rubber punches are widely used and are applicable to extremely difficult operations or those impossible to do by other means. Rubber is selected at a hardness, tensile strength, and deflection most suitable for the workpiece shape. The rubber punch or pad must be correctly shaped and located to apply pressure to the shell wall at the required points; it must be kept free from oil; and it should be lubricated with talc, pumice, or other powder-type lubricant.

Water and oil can also be used to exert pressure directly against the workpiece, but this technique requires expensive tooling and controls and is often messy.

**Contracting or necking** operations reduce the diameter of a shell, usually at the open end. This entails reductions ranging in severity from the forming of a shallow circumferential groove to the forming of a bottleneck shape.

Reduction in diameter in a single operation should not exceed 8 to 15%, depending on alloy, temper, and extent of prior work hardening. The angle from the body to the necked diameter should be less than  $45^\circ$ , to prevent collapse of the

shell. It may be necessary to anneal the workpiece locally.

**Hole flanging**, the forming of a flange or collar around a hole in sheet stock, can be a critical operation. The hole should be punched from the side opposite the intended flange. This prevents splitting of the severely stretched outer edge of the flange. Splitting could be initiated by the burred edge of the hole.

Shallow-flanged holes can be produced in a single pierce-and-flange operation with a stepped punch. The edges of the pierced hole should also be as smooth as possible. Low-strength ductile alloys in the annealed temper will permit forming the deepest flanges and the sharpest bend radii.

**Beading** or ribbing is usually the most economical way to provide stiffness and avoid oil-can or buckling effects in large panels. Beads that extend from edge to edge of the workpiece are conveniently formed either by bending in a press brake or with corrugating rolls.

Beads that do not extend all the way across the part require a stretching or forming operation either with a rubber-pad die or in a punch press with a rigid punch and a rigid die. A double-acting die and a blankholder can be used to prevent wrinkling at the ends of the beads, and deep, parallel beads are often made one at a time. Rubber-pad forming can also be used, as can drop hammer forming for small quantities.

# Flanging of Aluminum

Jian Cao, Northwestern University

FLANGING is a process used to form a projecting rim or edge on a part. The process definition and the hardware needed in the operations of bending, flanging, and hemming are provided in the Section “Forming Processes for Sheet, Strip, and Plate” in this Volume. In this article, emphasis is given to how to determine the flanging limits in terms of fracture, wrinkling, and springback, and their influencing material and process parameters. Similar to the flanging process, hemming involves severe bending operations as well. Interested readers can refer to Ref 1 for an experimental study of hemming of aluminum 1050.

## Fracture

Bendability is often defined as the ratio of the thickness of the material to the minimum bend radius that a material can achieve before failure (Ref 2). Figure 1 shows a fractured aluminum autobody sheet resulting from a flat-hemming operation (Ref 3). It can be seen from Fig. 2, a micrograph of the outer surface of a bend specimen of 1.0 mm (0.04 in.) thick 6111-T4 sheet for a bend radius of 0.406 mm (0.016 in.), that the fiber at the outer surface is elongated quite significantly. It has been widely accepted that the well-known forming limit diagram is not suitable for predicting failure in bending, flanging, and hemming. The concept of the forming

limit diagram is explained in the article “Formability Testing of Sheet Metals” in this Volume. In general, 5xxx alloys have significantly better bendability than 6xxx alloys; however, they experience surface roughening on the outer surface of the bend sample that is similar to the 6xxx alloys (Ref 2).

In general, hemmability and bendability are primarily influenced by four factors: work hardening, constituent particles, grain-boundary precipitates, and surface roughening. Hemmability can be enhanced by more work hardening, less volume fraction, more uniformly distributed constituent particles, cleaner grain boundaries, smaller size of grain-boundary precipitates (especially avoiding plate-shaped grain-boundary precipitates), smoother as-rolled surface, and suppressed surface roughening in deformation (Ref 3).

**Example 1: Bendability Cannot be Measured from the Forming Limit Diagram.** In Fig. 2, a sheet of 1.0 mm (0.04 in.) thick 6111-T4 was bent to an arc with an inner radius of 0.406 mm (0.016 in.). A rough estimation of the strain along the circumferential direction accounting for the shift of neutral axis is:

$$\begin{aligned}\epsilon &= \ln \frac{r+t}{\sqrt{r(r+t)}} = \frac{1}{2} \ln \frac{r+t}{r} \\ &= \frac{1}{2} \ln \frac{0.406 + 1.0}{0.406} = 0.62\end{aligned}\quad (\text{Eq 1})$$

where  $r$  is bend radius, and  $t$  is thickness. This is way beyond the elongation limit of this material

obtained from a tensile test—23% recorded in the same study. The cause of this extra stretchability in bending is believed to be due to the high strain gradient across the thickness in this kind of tight bend. A closed-form solution for predicting this bendability is not yet available, because it highly depends on the microstructure of the material, for example, the size and distribution of precipitate particles. Dao and Li (Ref 3) attempted a crystal-plasticity-based computational approach to study the localization and fracture initiation modes in bending of aluminum sheets, and they showed some success.

In 1992, Mnif studied the bendability of aluminum sheet AlMg0.4Si1.2 during a 90° straight flanging process (Ref 4). Figure 3 shows the results of his study when 1.25 mm (0.05 in.) sheets were subjected to uniaxial prestretching of 5, 10, and 15% in the bending direction and then bending with bend radii of 1, 2, 3, and 4 mm (0.04, 0.08, 0.12, and 0.16 in.) and a bend gap of 1.35 mm (0.053 in.).

**Example 2: Bend Performance of 6xxx Alloys.** Friedman and Luckey (Ref 2) experimentally investigated the bendability and surface roughness of several aluminum alloys, including 6111-T4 (Al-0.82 Si-0.26 Fe-0.59 Cu-0.20 Mn-0.58 mg) and 6022-T4 (Al-0.82 Si-0.13 Fe-0.07 Cu-0.06 Mn-0.60 mg). Figure 4 shows the initial yield stresses and the ultimate stresses along the longitudinal and transverse directions for these

two alloys. As can be seen from Fig. 5, interestingly, the bendability (a good bendability is indicated by a low value of  $r/t$  in the figure) of 6111-T4 is better than that of 6022-T4 when the prestrain is lower than 5%. Once the prestrain exceeds 5%, the trend is reversed. This phenomenon is expected to be related to alloying of the two different aluminum materials. More research is needed to find out the exact cause.

## Wrinkling

Wrinkling in shrink or convex flanging can be problematic in the flanging area as the outer edge is compressed. Figure 6 shows the setup and a before-and-after flanged sheet. These wrinkles can significantly reduce the assembly accuracy. Furthermore, wrinkles are sometimes pressed (or ironed) out when the clearance between the punch and the die is small. This complicates the deformation history and generates an uneven stress distribution in the sheet, which makes the accurate prediction of springback (or distortion) extremely difficult.

Theoretical prediction of the wrinkling limit in shrink flanging has been specifically studied (Ref 5, 6). In Ref 5, the critical wrinkling strain was derived as:

$$\varepsilon_{\theta}^{\text{cr}} = \left\{ \frac{1}{3} \left( \frac{t}{R_2} \sin \alpha \right)^2 \frac{E}{K} n \right\}^{\frac{1}{n+1}} - \varepsilon_0 \quad (\text{Eq 2})$$

where  $K$  and  $n$  are the material parameters in the power law to describe the material hardening

**Fig. 4** Mechanical properties of 6111-T4 and 6022-T4. L, longitudinal; T, transverse; UTS, ultimate tensile strength

(a)

behavior ( $\bar{\sigma} = K\bar{\varepsilon}^n$ ),  $t$  is the sheet thickness,  $\varepsilon_0$  is the prestretching amount in the sheet before the flanging process,  $R_2$  is shown in Fig. 7, and  $E$  is Young's modulus.

Wang et al. (Ref 6) investigated the wrinkling limit of aluminum shrink flanging and compared the results to the experimental study conducted by Li at Alcoa, which is summarized here. More details can be found in their paper. The approach used in the analysis was based on the energy method. The material hardening behavior was modeled with Voce's law:

$$\bar{\sigma} = A - B \exp(-c\bar{\varepsilon}) \quad (\text{Eq 3})$$

which describes the aluminum sheet very well. The stress,  $\sigma_{\text{applied}}$ , corresponds to the maximum compressive hoop stress in the flange sheet and can be calculated as:

$$\sigma_{\text{applied}} = A - B \times \exp\left(-c \sqrt{\frac{2(1+R)}{1+2R}} \ln\left(\frac{R_f + f_l \sin \beta}{R_0}\right)\right) \quad (\text{Eq 4})$$

where  $A$ ,  $B$ , and  $c$  are material parameters in Voce's law (Eq 3),  $R$  is the planar anisotropic factor,  $R_f$ ,  $f_l$ , and  $R_0$  are geometric parameters (Fig. 6a), and  $\beta$  is the folding angle shown in Fig. 8.

This applied stress,  $\sigma_{\text{applied}}$ , should be compared with the critical buckling stress,  $\sigma_{\text{cr}}$ . Wrinkling is assumed to occur when  $\sigma_{\text{applied}}$  is

**Fig. 5** Bend performance ( $r/t$ ) for both 6xxx alloys in the longitudinal orientation as a function of prestrain

(b)

greater than  $\sigma_{\text{cr}}$ . The calculation of  $\sigma_{\text{cr}}$  is more complicated and out of the scope of this work, but an executable program is available from the author. Note that the program is suitable for large panels, that is, when the planar radius is significantly larger than the sheet thickness.

**Example 3: Shrink Flanging of 6111-T4.** The example here was presented in Ref 6. Table 1 shows the material properties for inputting to the aforementioned executable program. Table 2 shows the comparison of wave number (i.e., number of wrinkling peaks) obtained from simulations and experiments, where plane view radius is the  $R_f$  in Fig. 6(a), and  $f_l$  is the flange length.

## Springback

Earlier experimental and analytical work on springback in the straight flanging process was

**Fig. 7** Schematic of flanging process parameter definitions used in Eq 2. Source: Ref 6

mainly concentrated on steel alloys, such as the study in Ref 7. Recently, as aluminum alloys are being increasingly used in automotive applications, experimental study of springback in flanging aluminum has been reported in literature, including straight flanging of aluminum AlMg0.4Si1.2 (Ref 4), shrink flanging of 1015 (Ref 1), straight flanging of 6111 (Ref 8), and straight flanging of 5182 (Ref 9). In addition, the shape distortion of aluminum 6111-T4 in shrink/stretch flanging has been reported (Ref 10). Figures 9 to 14 collectively show the springback values reported in the aforemen-

tioned studies on straight flanging. In general, the springback angle increases as the gap between the punch and the die increases and as the bend radius increases, except for the case when 15% prestretching was imposed (Ref 4) (Fig. 9). In Ref 9, a straight flanging experiment with alloy 5182 was conducted. The relevant material properties of this material are listed in Table 3. The dimension of the 1 mm (0.04 in.) thick samples was 150 by 150 mm (6 by 6 in.) (width and length), and the flange length of the samples was 20 mm (0.8 in.). The die corner radius was 3 mm (0.12 in.). The

binder force was set to approximately 460 kN (103,000 lbf). The effect of gap on springback is presented in Fig. 13. Each isolated symbol represents one experimental datum, and various finite element models and material models were compared. A trend of major parameters to springback is summarized in Fig. 14. Prediction of springback in flanging is not an easy task, because sheet material is under large deformation of bending and unbending. The fundamental recovery mechanism has not been

well understood. For straight flanging processes, a number of analytical springback-prediction models have been proposed (Ref 9, 11, 12). The key mechanism assumed in all those models was that the work done during the forming process is reversed elastically during the springback step. An analytical model for springback prediction in Ref 12 is available (Ref 13) with the following main assumptions: plane strain, isotropic material, power hardening law ( $\sigma = K\epsilon^n$ ), and the same tensile and compressive behavior. It is important to point out that common engineering sense needs to be applied when interpreting the result obtained from the program, especially when the thickness or panel geometry is significantly different from those used in the illustrations.

In Ref 1, shrink flanging of alloy 1050 was investigated. Relevant properties are given in Table 3. The experimental setup is presented in Fig. 15. No effect of binder force was studied in the experiment.

**Fig. 14** Summary of the general trends of die corner radius, punch-nose corner radius, gap, and binder force on springback angle. Source: Ref 8

**Fig. 15** Experimental setup for an aluminum shrink flanging study. Source: Ref 1

Varying the shrinking radius ( $x$ -axis:  $R_{sh}$ ) and flange length ( $h$ ), different springback angles are obtained and shown in Fig. 16. One can observe that if the flange length ( $h$ ) is large enough, less springback variation is developed. Additional information is provided in the article "Springback" in this Volume.

## Conclusions

This article reviews several common concerns with designs involving aluminum flanging, that is, fracture, wrinkling in shrink flanging, and springback in straight and shrink flanging. Each of these phenomena depends on material conditions and process parameters, such as the surface finish of sheet metal, tooling radii, gap between the punch and the die, and so forth, as illustrated previously. Readers are encouraged to explore more details in the references and in recent conference publications.

# Forming of Beryllium

BERYLLIUM has been successfully formed by most common sheet metal forming operations. The following are required:

- Equipment that can be controlled at slow speeds and that can withstand the use of heated dies
- Dies that can withstand the temperatures at which beryllium is commonly formed
- Facilities for preheating and controlling the temperature of dies and workpieces
- In some applications, facilities for stress relieving the work at 705 to 790 °C (1300 to 1450 °F)
- Special lubrication
- Safety precautions when grit blasting is required for cleaning after forming

Almost all beryllium currently used is produced by consolidating beryllium powder into a block by vacuum hot pressing. The powder is obtained by chipping and then mechanically or pneumatically pulverizing a vacuum-cast ingot. The hot pressed block can be warm rolled to the desired sheet thickness.

Unalloyed beryllium is available in two grades, I (instrument grade) and S (structural grade). Typical applications for instrument-grade beryllium include gyroscopes, components in inertial guidance systems, and precision satellite and airborne optical components. Structural grades find application as satellite superstructures, antenna booms, and optical support structures. Table 1 lists the compositions of four grades of vacuum hot pressed beryllium.

## Formability

The formability of beryllium is low compared with that of most other metals. Beryllium has a hexagonal close-packed crystal structure; thus,

there are relatively few slip planes, and plastic deformation is limited. For this reason, all beryllium products should be formed at elevated temperature (generally 540 to 815 °C, or 1000 to 1500 °F) and at slow speeds.

Temperature, composition, strain rate, and previous fabrication history have marked effects on the results obtained in the forming of beryllium.

**Effect of temperature** on formability (in terms of bend angle at fracture) of two grades of powder sheet is shown in Fig. 1. Although these data show the effect of temperature on bendability, maximum strain on a  $2t$  bend radius is not achieved at less than 90°. Therefore, it should not be assumed that the quantitative results shown in Fig. 1 can always be applied directly in practice.

It should be noted that Fig. 1 was generated using beryllium sheet with a guaranteed elongation of only 5%. Current beryllium sheet products have guaranteed room-temperature elongations of 10%; typical values of 15 to 20% indicate that, if the test illustrated in Fig. 1 were repeated today (2005), improvement in results would be significant. In one case, a 90° bend with a  $2t$  radius was achieved in 0.5 mm (0.020 in.) thick beryllium sheet.

**Effect of Composition.** The oxide content of ingot and powder sheet has a significant effect on formability, as shown by the curves in Fig. 1. As the oxide content increases, yield strength increases and ductility decreases.

**Effect of Strain Rate.** Strain rate greatly influences the formability of beryllium. For instance, the stroke of a press brake is too fast for making sharp bends in hot beryllium. Slow bending, by means of equipment such as a hydraulic or air-operated press, is usually used. Minimum bend limits for the press-brake method and the slower-press method are compared in Fig. 2 for bending of cross-rolled powder sheet.

In a laboratory, a radius of  $2\frac{1}{2}t$  was bent in beryllium sheet at the rate of 50 mm/min (2 in./min), and a radius of  $5\frac{1}{2}t$  at 305 mm/min (12 in./min). Forming temperature in both cases was 745 °C (1375 °F).

**Effect of Fabrication History.** Beryllium products consolidated by vacuum hot pressing have low ductility, even at a theoretical density of 100%. The ductility of hot pressed beryllium can be increased by hot mechanical working.

Fig. 1 Bend angle to fracture versus temperature of beryllium sheet using a  $2t$  bend radius

Fig. 2 Minimum bending limits for press-brake versus slower (hydraulic) bending of beryllium sheet in transverse and longitudinal directions.  $r$ , bend radius;  $t$ , sheet thickness

(a) Maximum, unless otherwise indicated

## Equipment and Tooling

Presses operated by air or hydraulic systems are usually used for forming beryllium, because of the slow speeds required. Standard mechanical presses or other fast forming presses are not suitable.

Critical components of the equipment must be protected against damage by the heat of forming. This protection usually is achieved by means of simple insulation.

**Tooling.** Because the tools used for forming beryllium will be heated, allowances must be made for thermal expansion, high-temperature strength, and oxidation when selecting tool material and designing tools. Tooling requirements for forming beryllium are similar to those for hot forming titanium (see the article "Forming of Titanium and Titanium Alloys" in this Volume). When only a few pieces are required, mild steel is usually used for dies. However, mild steel oxidizes rapidly at elevated temperatures, and when more than a few identical pieces are to be formed, the best practice is to make dies from hot work die steels, stainless steel, or one of the nickel-base or cobalt-base heat-resistant alloys.

## Heating Dies and Workpieces

In most forming applications, both the die and the workpiece must be preheated. Dies are specially constructed to permit heating; heat may be supplied by either electrical elements or gas burners. Although sometimes torches are satisfactory for heating the work (as when heating sheet for spinning), usually a furnace is preferred. No specially prepared atmosphere is needed.

At the maximum temperature used for forming beryllium, surface oxidation is usually negligible. However, if desired, to prevent surface discoloration (hard oxide layer), the workpiece can be coated with a film of commercial heat-resistant oil. After forming, the film of oil can be removed by wet blasting, or by degreasing with an agent such as trichloroethylene.

In the forming of thin sheet (less than ~1 mm, or 0.040 in., thick), cooling of the work between the furnace and the forming equipment is often a problem. Overheating to compensate for this heat loss is not recommended. One satisfactory solution is to "sandwich" thin sheets of beryllium between two sheets of low-carbon steel. This sandwich is retained throughout heating and forming.

## Stress Relieving

Stress relieving between stages of forming, or after forming is completed, is needed only in the forming of relatively thick sheet or in severe forming. For some finish-formed parts, stress relieving has proved an effective means of

counteracting "oil canning" or excessive warpage. When stress relieving is used, regardless of whether it is an intermediate step or a final operation, holding at 705 to 760 °C (1300 to 1400 °F) for 30 min is recommended. No specially prepared atmosphere is needed.

## Lubrication

Lubrication or coating of some type is needed in most beryllium forming operations. For less severe operations, such as bending, powdered mica has been used.

For operations such as joggling, forming in matched dies, or deep drawing, colloidal graphite in oil is commonly used. The role of lubrication is especially critical in deep drawing and is discussed in more detail in the section "Deep Drawing" in this article.

## Safety Practice

No special precautions or safety measures are required in forming of beryllium because no fines or oxide dust is created in forming; and the maximum temperature (815 °C, or 1500 °F) used for preheating causes the formation of only a thin film of hard oxide, which under normal operating conditions will not harm personnel. Extreme caution should be used, however, and safety equipment should be available in the event of a furnace overrun.

However, if parts require cleaning after forming and if grit blasting is used, the wet method is recommended. Wet blasting minimizes the possibility that beryllium oxide dust will contaminate the surrounding atmosphere. Adequate ventilation must be provided if parts are processed by chemical etching after forming.

The usual precautions observed in working with beryllium must be taken. Details on protection can be obtained from the publication "Health Protection in Beryllium Facilities," which is available from the U.S. Atomic Energy Commission. Also, a video tape, "Beryllium: Safe Handling," is available through Brush Wellman Inc.

## Deep Drawing (Ref 1)

Deep drawing is the forming of deeply recessed (cuplike) parts by means of plastic flow of the material (see the article "Deep Drawing" in this Volume). Tooling consists of a punch and a suitable die or draw ring. Normally, the deformation in deep drawing is actually a combination of deep drawing and stretching.

There are two parameters that must be under control during any successful deep-drawing operation: friction and holddown pressure. Both can be controlled by proper die design and lubricant selection, as discussed subsequently.

**Lubrication** is required to prevent galling between the beryllium workpiece and the die. A lubricant film must be maintained over that portion of the blank surface making contact with the drawing surfaces of the die throughout the entire draw. Because elevated temperatures (595 to 675 °C, or 1100 to 1250 °F, for the workpiece; 400 to 500 °C, or 750 to 930 °F, for the dies) are required to deep draw beryllium, conventional lubricants applied directly to the blank and die will burn off, causing galling between workpiece and die at high-pressure areas such as the draw ring. The solution to this problem is best achieved by using die materials that are self-lubricating, such as graphite or an overlay of colloidal suspension of graphite on an asbestos paper carrier.

The technique of using consolidated graphite as a self-lubricating die material was initially developed for forming small, thin-walled parts to finished size. This technique has evolved to the point that very deep drawing of 6.35 mm (0.25 in.) thick blanks over a graphite draw ring is routine. The disadvantage is that such draw rings have short service life.

Organic emulsified suspensions of powdered graphite, aluminum, and copper have all been used successfully to lubricate punches to facilitate part stripping. These materials can also be applied to the draw ring to improve lubricity of the drawing surface under the graphite-impregnated paper.

**Blank development** for deep drawing of beryllium generally follows the same rules as for other metals. Blanks too thin to support themselves during the early stages of drawing will buckle or wrinkle. A restraining force is required to prevent this.

There are numerous factors involved in determining whether blank restraint is required during any drawing operation. The two most important are the ratio of blank diameter  $d$  to blank thickness  $t$  and the percentage of reduction from one draw to the next.

The relationship between reduction  $R$  and  $d/t$  is shown in Fig. 3 for cylindrical parts, whether they are flat-bottomed or hemispherical cups. The areas under the curves were determined experimentally, with the curves themselves being the normal limit of formability for a given reduction at a given  $d/t$  ratio.

The curves in Fig. 3 describe formability limits; therefore, some consideration should be given during design to avoid borderline cases. Reductions of more than 50% are possible but will require partial drawing followed by several anneals, usually with a high failure rate. Several stages of tooling requiring smaller reductions is a more practical approach.

**Tool Design.** There are many different tool designs for deep drawing sheet metal parts. Two general types are described here. One type does not apply blank restraint to prevent wrinkling and is referred to as single action. The other type does apply blank restraint and is referred to as double action.

Single-action tooling should be used to form parts that fall in the no-restraint section of Fig. 3. Double-action tooling, or tooling that applies blank restraint to avoid wrinkling, was developed in two forms. In one system, the lower cushion ram in a hydraulic press is used as the second action for blank restraint (Fig. 4). The other type of double-action tooling used to deep draw beryllium is described in detail in Ref 1.

Materials used for beryllium deep-drawing tooling need not be exotic. Gray cast iron is satisfactory for most punch and die applications. Drawing surfaces are usually made from a free-machining tool steel or, in the case of very large dies, low-carbon steel that has been carburized after machining.

**Strain rates** during deep drawing of beryllium may vary widely, depending on the severity of the draw. For deep drawing simple hemispherical shells, punch speeds of 760 to 1270 mm/min (30 to 50 in./min) are commonly used. With optimal die clearance and lubrication, strain rates in excess of 2500 mm/min (100 in./min) have been observed in successful deep draws.

**Applications.** Numerous shapes have been deep drawn from beryllium. Considerable material savings may be achieved by deep drawing rather than machining thin-walled parts. The process lends itself to cup-shaped parts that have a slightly thicker wall at the equator than at the pole because of thickening in this area during forming.

### Three-Roll Bending (Ref 1)

Three-roll bending is a process for shaping smoothly contoured, large-radius parts by applying three-point bending forces progressively along the part surface (see the article "Three-Roll Forming" in this Volume). Usually,

one or more of the forming rolls is driven. The process has been used to form curved panel sections and full cylinders from beryllium. As in all forming operations for beryllium, it is necessary to heat the blank to achieve the necessary ductility to avoid cracking.

**Applications.** Three-roll bending has been used to form precision beryllium cylinders. The cylinders were joined by an electron beam fusion weld and are round within 0.5 mm (0.02 in.) total indicator reading on the diameter.

Panels for the Agena spacecraft also have been formed to a 762 mm (30 in.) radius of curvature. There were two sizes of panels formed, 635 by 635 mm (25 by 25 in.) and 559 by 355 mm (22 by 14 in.), at thicknesses of 1.4 and 1.88 mm (0.055 and 0.074 in.), respectively, from cross-rolled beryllium powder sheet. The flat beryllium sheet was heated to approximately 427 °C (800 °F), placed on a stainless steel sheet somewhat longer than the beryllium, and manually rolled to contour. The stainless steel sheet was used to "lead in" the beryllium and reduce the flat end inherent to roll forming. The rolled panels were stress relieved at 732 °C (1350 °F) for 20 min.

### Stretch Forming (Ref 1)

Stretch forming is the shaping of a sheet or part, usually of uniform cross section, by first applying suitable tension or stretch, then wrapping it around a die of desired shape (see the article "Stretch Forming" in this Volume). When applying this technique to beryllium, the wrapping operation usually takes place quite slowly.

**Tooling.** Two commonly used types of tooling to stretch form beryllium are generally described as open-die and closed-die tooling. Open die, the most common, consists of a

male die with the desired contour and some means of forcing the blank to assume that contour. Tension is not normally required for beryllium because the high modulus resists buckling and wrinkling.

Closed-die tooling has male and female counterparts. The male die is used to force the blank into the female die, thereby causing the blank to assume the contour of the male die. This type of tooling lends itself well to beryllium forming because both portions of the die may be heated to facilitate maintenance of the heat necessary in the blank to avoid cracking. Friction forces on the female die can help to restrain the part and cause stretching.

### Spinning

Beryllium sheets up to 5.1 mm (0.200 in.) thick have been successfully formed by spinning. For sheets less than approximately 1 mm (0.040 in.) thick, a common practice is to sandwich the beryllium between two 1.5 mm (0.060 in.) sheets of low-carbon steel and heat the sandwich to 620 °C (1150 °F) for spinning. The steel sheets not only help to maintain temperature but also help to prevent buckling. Beryllium sheets more than approximately 1 mm (0.040 in.) thick usually are not sandwiched between steel sheets for spinning and are heated to 730 to 815 °C (1350 to 1500 °F).

Hemispherical shapes have been spun in as many as nine stages with no adverse effect on the properties of the beryllium. The part and mandrel often are torch-heated during spinning.

Lubrication is especially important in spinning. Colloidal graphite or glass is usually used. Wet blasting is the recommended means of cleaning the workpiece after spinning.

**Fig. 3** Percent reduction in deep-drawing versus diameter-to-thickness ( $d/t$ ) ratio for deep drawing of cylindrical beryllium shells. Datapoints are experimental observations (double action or single action) used to derive the curve limits;  $d$ , blank diameter;  $t$ , blank thickness; shaded areas, marginal. Source: Ref 1

**Fig. 4** A double-action tool for deep drawing of beryllium that uses the action of the lower press action for blank restraint. Lubrication with this type of tooling is best achieved using asbestos paper impregnated with colloidal graphite (see inset). Source: Ref 2

**Fig. 5** Dimensional combinations for the successful spinning of beryllium sheet.  $d_0$ , blank diameter;  $d_1$ , diameter of spun part;  $t$ , blank thickness;  $h$ , height of spun part

Figure 5 plots combinations of conditions under which parts of a variety of shapes have been successfully produced by spinning cross-rolled beryllium powder sheet. The points plotted, however, represent only limited data, and many more points would have to be established before it would be safe to designate dimensional limitations for spinning specific shapes. More information on the spinning process is available in the article "Spinning" in this Volume.

# Forming of Copper and Copper Alloys

Frank Mandigo and Derek Tyler, Olin Corporation

COPPER AND MOST COPPER ALLOYS are readily formed at all sheet gages. The copper alloys commonly formed are characterized by strength and work-hardening rates between those of steel and aluminum alloys. This article reviews the general characteristics of copper and copper alloys and how these characteristics affect the behavior of strip in different types of forming operations. The attempt is to provide an understanding of copper alloy formability coupled with illustrative data rather than to offer a complete single-source alloy data reference.

## General Considerations

The combination of moderate-to-high strength, high electrical and thermal conductivity, stress-relaxation resistance, modest cost, good corrosion and stress-corrosion resistance, and ease of plating and joining, coupled with good formability, accounts for the use of copper and copper alloys in a wide range of applications. A list of forming operations typically used to fabricate various parts from copper and copper alloy strips is as follows:

Application	Forming operations
Electrical terminals and connectors	Bending, stretch forming, blanking, coining, drawing
Electronic leadframes	Bending, coining, blanking
Hollow ware, flatware	Roll forming, blanking
Builder's hardware	Shallow and deep drawing, and stretch forming operations
Heat exchangers	Roll forming, bending, sinking, blanking
Coinage	Blanking, coining, embossing
Bellows, flexible hose	Cupping, deep drawing, bending
Musical instruments	Blanking, drawing, coining, bending, spinning
Ammunition	Blanking, deep drawing

These applications are illustrated in Fig. 1 to 8.

The forming of any part involves the interaction of material, tooling, and lubrication. Tooling and lubrication are discussed in the articles "Presses and Auxiliary Equipment for Forming of Sheet Metal" and "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume and are noted in this article only where there are unique or specific requirements for a copper alloy or a given forming operation. The

forming characteristics of copper and copper alloys are discussed at length. All of the various major forming operations considered in this article—blanking, bending, stretch forming, drawing, and coining—depend on some optimal combination of strength, ductility, and work-hardening behavior of the sheet metal to provide the most cost-effective part. Therefore, much of this article is devoted to understanding the trade-offs in strength, work hardening, and ductility available by selection of material composition and temper. Strain-rate sensitivity ( $m$ ) is also a factor in some forming operations. However,  $m$  is of practical significance only at elevated temperature. A more comprehensive treatment of the relationships between these materials characteristics and formability is available in the article "Formability Testing of Sheet Metals" in this Volume and in the article "Bend Testing" in *Mechanical Testing and Evaluation*, Volume 8 of *ASM Handbook*, 2000.

Other test methods used to assess sheet metal forming characteristics are the plastic-strain ratio ( $r$ ), which is a measure of sheet anisotropy; the limiting draw ratio (LDR); bulge height; and minimum bend-forming radius. Comparison of test results can provide a relative ranking of the deep draw and/or stretch forming capabilities of various alloy compositions in different temper conditions.

**Effects of Composition, Cold Work, and Heat Treatment on Formability.** Copper alloys are primarily strengthened by cold work or by alloying additions that solid-solution strengthen and enhance strain hardening. A finely dispersed second phase is sometimes used as a grain refiner to increase strength/ductility combinations and/or to minimize or prevent surface roughening ("orange peel") during forming.

Precipitation hardening is important to a small but important class of alloys, most notably, the beryllium-copper and copper-nickel-silicon alloy systems. Spinodal and/or precipitation hardening is available in the copper-nickel-tin, copper-nickel-chromium, and copper-titanium systems. Hardening by martensite transformation is available in the copper-aluminum system but is rarely used commercially.

Copper alloys are classified using the Unified Numbering System (UNS). The designations of the Copper Development Association are also

used and correspond closely to UNS designations. Wrought copper alloys are divided in the UNS system into the following groups:

Alloy type	UNS No.
Copper and high-copper alloys	C1xxx
Zinc brasses	C2xxx
Zinc-lead brasses	C3xxx
Zinc-tin brasses	C4xxx
Tin bronzes	C5xxx
Aluminum, manganese, and silicon bronzes	C6xxx
Copper-nickel and copper-nickel-zinc alloys	C7xxx

UNS numbers, common alloy names, and the nominal alloy chemistries of the principal copper alloys are listed in Table 1.

The temper designations for solid-solution-strengthened and precipitation-hardened copper and copper alloys are reviewed in the sections "Solid-Solution Strengthening and Cold Working" and "Precipitation Hardening and Cold Working" in this article.

**Solid-Solution Strengthening and Cold Working.** Solute elements provide a major means of strengthening copper, and the magnitude of strengthening depends on the type and level of addition. Temper designations for solid-solution-strengthened copper and copper alloys are listed in Table 2. Table 3 lists mechanical properties resulting from various alloying additions to copper in the annealed condition. These data indicate strength higher than that of pure copper (alloy C11000) can be acquired with limited or no loss of tensile ductility by solid-solution alloying. A listing of properties that can be typically expected is available in the article "Properties of Wrought Coppers and Copper Alloys" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2 of *ASM Handbook*, 1990. Suppliers of copper and copper alloy strip should be consulted for specific property/temper characteristics.

Figure 9 shows the work-hardening behavior of copper (C11000) and several copper alloys in terms of strength and ductility versus cold reduction. The relative work-hardening effects of various alloying elements are evident; the strong effect of aluminum is contrasted with the weak effect of nickel, with zinc and tin being intermediate. Ductility, as indicated by tensile elongation, decreases with cold reduction. Again, however, the combination of strength and

(a)

(b)

**Fig. 1** Electrical and electronic applications for formed copper alloy parts. (a) Connectors used in home appliances and automotive electrical systems. (b) Copper alloy leadframe for a semiconductor device

**Fig. 2** Typical household flatware utensils formed from copper alloys

ductility is enhanced by solid-solution additives even after cold working.

**Precipitation Hardening and Cold Working.** Alloys containing beryllium (0.15 to 2.0% Be) with nickel (0.3 to 2.7% Ni) or cobalt (1.0 to 2.2% Co) or alloys with nickel (1.0 to 3.5% Ni) and silicon (0.25 to 0.80% Si) can be strengthened by solid-state precipitation. Alloys with high beryllium content (1.8 to 2.0%) can be cold worked and precipitation hardened to produce material with tensile strength above 1380 MPa (200 ksi) at 15 to 28% International Annealed Copper Standard (IACS). In 1913, values of electrical conductivity were established and

expressed as a percent of a standard. The standard chosen was an annealed copper wire with a density of 8.89 g/cm<sup>3</sup>, a length of 1 m (3 ft), a weight of 1 g, with a resistance of 0.1532 Ω at 20 °C (70 °F). The 100% IACS value was assigned with a corresponding resistivity of 0.017241 Ωmm<sup>2</sup>/m. The percent IACS for any material can be calculated by:

$$\%IACS = \frac{0.017241 \, \Omega \, \text{mm}^2/\text{m} \cdot 100}{\rho_v}$$

where  $\rho_v$  is volume resistivity.

Alloys with lower beryllium contents provide tensile strengths from 655 to 965 MPa (95 to 140 ksi) with better thermal and electrical conductivities (45 to 60% IACS). Alloys with nickel and silicon additions can provide tensile properties from 585 to 860 MPa (85 to 125 ksi) with electrical conductivities from 35 to 60% IACS. A listing of properties that can be typically expected for precipitation-hardened copper alloys is available in the articles "Properties of Wrought Coppers and Copper Alloys" and "Beryllium-Copper and Other Beryllium-Containing Alloys" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2 of *ASM Handbook*, 1990. Suppliers of precipitation-hardened copper alloy strip should be consulted for specific property/temper characteristics.

Precipitation-hardenable alloys offer the opportunity to form parts in the maximum-ductility (as-solution heat treated) conditions prior to final precipitation hardening to develop maximum strength. Part geometry, platings or coatings on the surfaces of copper alloy strip, volume changes that may occur during precipitation-hardening treatments, overall cost, and/or fabrication requirements are factors that determine whether forming precedes or follows the final precipitation-hardening treatment of precipitation-hardened copper alloys. Typically, only parts that require sharp bends or have very severe formability requirements are fabricated

from strip in the annealed or rolled tempers prior to final precipitation hardening. Electrical connector parts are typically fabricated from precipitation-hardened copper alloys in mill-hardened tempers to minimize cost (customer heat treatment, cleaning, and/or surface plating or coating steps). Temper designations for precipitation-hardenable copper alloys are provided in Table 4.

The mechanical properties of exemplary precipitation-hardenable alloys in the solution-annealed condition are given in Table 5. The work-hardening behavior of several precipitation-hardening systems in the solution-annealed condition is shown in Fig. 10. The strong effect of beryllium content on work hardening is evident in Fig. 10 for alloy C17200. Table 6 lists the mechanical properties of selected tempers of mill-hardened alloys.

**Postforming Heat Treatment.** Heat treatments, aside from those employed to precipitation harden, are used after forming to reduce susceptibility to stress corrosion (primarily the brasses) or to increase the stiffness or stress-relaxation resistance of electrical or electronic springs (mainly the brasses, aluminum bronzes, and copper-silicon alloys). These postforming treatments are performed at low temperatures.

## Formability of Copper Alloys versus Other Metals

In forming a given part, no single materials property completely defines formability. As previously noted, formability can best be rationalized in terms of the strength, work hardening, and ductility of a copper alloy, but these parameters do not directly correlate with formability. The problem becomes even more difficult when comparing different alloy systems, for example, ferrous and nonferrous.

Figure 11 shows the annealed ultimate tensile and yield strengths and response to cold rolling

(a)

(b)

**Fig. 3** Builder's hardware formed from copper alloys. (a) Doorknob fabricated by deep drawing. (b) Recessed fixture for kitchen and bathroom accessories

**Fig. 4** Automotive radiator fabricated from several formed copper alloy components, including a deep-drawn water tank, roll-formed cooling tubes, and formed cooling fins

for type 304 stainless steel, 1045 steel, aluminum alloy 1100, copper alloy C11000, and other selected copper alloys. The high work-hardening rate and strength of the austenitic stainless steel are evident. The copper alloys range from above aluminum to above medium-carbon steel in strength and work-hardening rate. A comparison of limiting draw ratio with the plastic-strain ratio ( $r$ ) for ferrous and nonferrous alloys is shown in Fig. 12. Increasing values of  $r$  and LDR reflect increasing drawability (see the section "Drawing and Stretch Forming" in this article).

In general, copper alloys typically offer better combinations of strength, formability, electrical conductivity, corrosion, ease of joining and plating, and/or stress-relaxation performance when compared to most other alloy systems.

Accordingly, copper alloy strips are replaced by other materials (aluminum, steel, stainless steel, or plastic) only when economics (material and/or fabrication costs) dictate or if the stamped part does not require a unique property (such as moderate electrical conductivity or ease of joining and plating) offered by copper alloy strip.

### Blanking and Piercing

**Nature of the Operation.** Blanking, piercing, and related cutting operations (trimming, notching, parting, and so on) are often used to provide parts that are subsequently formed to final shape by such operations as bending, drawing, coining, and spinning. Cutting oper-

**Fig. 5** Copper alloy U.S. currency with heavy coining and embossing

ations are frequently conducted in the same press tooling used to form and shape the final part geometry. The principal objective of any cutting operation is to produce a workpiece that has the correct geometric shape, is free of distortion, and possesses sheared edges that are of sufficient quality to allow subsequent forming, finishing, and/or handling operations.

**Materials Considerations.** Copper and copper alloys can be readily blanked and pierced. The quality of the final part produced and the ease of fabrication of the part are dependent on the flatness and dimensional tolerances (width, thickness, and so on) of the initial strip as well as the quality of the blanked or cut edge of the strip. The flatness and dimensional tolerances of copper alloy strip are dependent on the equipment and manufacturing expertise of the strip supplier. The quality of the blanked or cut edges—shear-to-break, rollover, breakout angle, burr height,

and so on—is determined by die clearance, die sharpness, and material characteristics.

**Effects of Alloy Composition and Temper.** Burr-free and distortion-free parts can be cut from annealed copper alloy strip at die clearances to approximately 5% of strip thickness. Unalloyed coppers, such as C10100 and C10200, require smaller clearances (usually <5%) and less latitude in actual values to produce burr-free edges, even in rolled tempers. Copper alloys that contain second-phase particles (for example, C19400) that have high solute additions (such as C26000 or C51000) and/or that are cold rolled more than 50% generally exhibit high-quality blanked edges at die clearances in the range of 3 to 12%. Low-lead additions to brass and other

copper alloys will decrease burrs and the shear-to-break ratio in blanking operations, but at some cost to formability in almost all types of forming operations.

## Bending

**Nature of the Operation.** Many connectors, terminals, and springlike components are fabricated by simple bending operations. Bending is a forming method in which a blanked coupon is wrapped, wiped, or stretched over a die to a specified radius and bend angle. Bend formability is usually expressed as minimum bend radius  $R$  in terms of strip thickness  $t$  ( $R/t$ ). Minimum bend radius is defined as the smallest radius around which a specimen can be bent without cracks being observed on the exterior bend (tension) surface. Bend deformation is highly localized and is confined to the region of the workpiece in contact with the bending die. Workpiece thickness is not substantially reduced unless the bend radius is less than  $1.0t$  or the part is coined or stretched during bending. A detailed review of bend testing is provided in the article “Bend Testing” in *Mechanical Testing and Evaluation*, Volume 8 of *ASM Handbook*, 2000.

**Materials Characteristics.** Ductility is the principal materials factor that determines bend formability. The ductility factor of first-order importance is the ability of a material to distribute strain in a highly localized region, that is, necking strain. The necking strain available depends on alloy composition and temper. As strength is increased by cold work, the ability of

an alloy to distribute necking strain decreases. The extent to which bend formability (necking strain) is decreased with increasing strength is dependent on the alloy composition and the strengthening mechanism. Conventional tensile elongation cannot be used to predict bend formability, because it does not adequately account for the contribution of necking strain. However, if the tensile specimen gage length were decreased to define an area of deformation equal to that deformed during bending, comparable ductility values would be obtained.

**Effect of Alloy Composition, Temper, and Orientation.** Bend data for a wide range of copper alloys are summarized in Table 7. Strength-to-bend formability characteristics are dependent on alloy composition, temper, and orientation. The principal strengthening mechanism is through solute additions to increase the work-hardening rate. For example, additions of 15 and 30% Zn to copper increase the tensile-strength-to-bend properties by 220 and 290 MPa (32 and 42 ksi), respectively, for 0.25 mm (0.010 in.) thick good-way bends at a bend radius of 0.4 mm ( $1/64$  in.). Precipitation strengthening is also an important mechanism employed to improve the strength-to-bend performance of copper alloy strip, particularly if the part is bent in a softer temper and subsequently precipitation age hardened to a higher strength.

The practice of cold rolling to increase strip temper degrades bend formability. However, it is often used because most alloys still exhibit useful bend formability at modest cold rolling reductions. Product applications that require both high strength and good bend performance are usually satisfied by selecting copper alloys that are precipitation and/or solute strengthened with additions that greatly increase the work-hardening rate and thus minimize cold rolling requirements to achieve the desired strength.

Bend formability is typically dependent on bend direction with respect to strip-rolling direction (Fig. 13 and Table 7). All cold-rolled materials exhibit directionality. The extent of bend directionality varies from alloy to alloy but always increases with increasing cold reduction.

Bend directionality results from the development of strong textures during rolling. Copper alloys with low stacking fault energy, such as alloy C26000 (cartridge brass), develop strong {110}<112> textures during rolling and can exhibit bend directionality even at approximately 30% cold rolling reduction. Dilute copper alloys and copper-nickel alloys do not develop well-defined rolling textures, and they show less bend directionality even at high (70%) cold rolling reductions. In general, sharper bends can be made in the good-way than in the bad-way orientations for alloys that are cold rolled and/or solute strengthened. Bend anisotropy in precipitation-hardening systems is strongly process dependent.

The bend performance of copper alloy strip is also dependent on bend angle, bend radius-to-strip-thickness ratio, and the width-to-thickness ratio of the bend regions of a stamped part. A 180° bend is more demanding than a 90° bend

**Table 3 Mechanical properties of selected solid-solution copper alloys**

Grain sizes of all materials listed ranged from 0.010 to 0.025 mm (0.0004 to 0.001 in.).

(a) Available only as tube, but properties are illustrative of copper-aluminum alloy strip properties.

when the  $R/t$  ratio of a strip is less than approximately  $2t$ . Typically, thin-gage strip,  $t < 0.15$  mm (0.006 in.), provides slightly better bend formability than strip at thicker gages,

$t > 0.38$  mm (0.015 in.). The bend performance of strip can be improved by as much as a factor of 3 or more in both good-way and bad-way orientations by reducing the width-to-thickness

ratio of the bend region of the part to less than 8 to 1.

Figure 14 shows the effects of bend directionality on part layout. This part includes both good-way and bad-way bends. If the part were fabricated from an alloy with strong bend directionality, for example, phosphor bronze (alloy C51000) in spring temper, the part layout would be restricted to avoid failure at bad-way bends. With alloys such as C68800 or C72500, which exhibit significantly less bend directionality, the part layout is not as restricted. It is not always possible to orient parts to minimize web scrap, regardless of the alloy selected, because tool design and part-handling and transfer costs may override the cost penalty of poor strip utilization.

**Special Considerations.** The minimum bend radii values listed in Table 7 for various alloys as

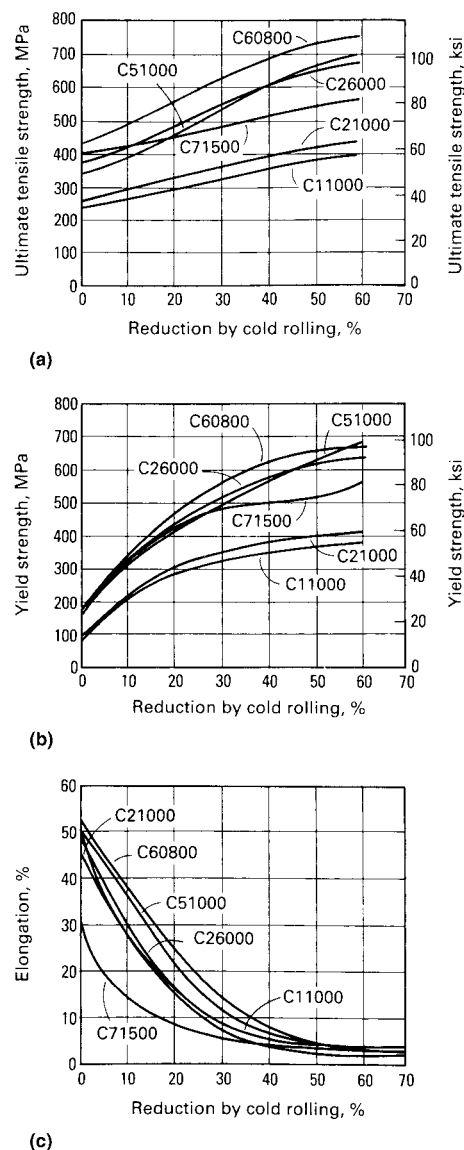

a function of temper are approximate; actual results are dependent on the tooling and stamping methods used. For example, bends can be made in one step or in multiple stamping steps with decreasing bend radii or by different methods (wipe or V-block) or with (different types) or without lubricant or with different tool materials (steel, carbide, coated tooling, etc.). Other examples of special considerations are parts to be plated after forming or subjected to other finishing operations after bending (no orange peel or surface roughening allowed) or plated and/or coated parts that have the requirement that no copper be visible at the exterior bend apex (no cracks in surface plating and/or coatings). Often, more than one alloy and

fabrication method is available that will meet product bend requirements. In the absence of other limitations, bend formability may be the deciding factor in alloy selection.

## Drawing and Stretch Forming

In drawing and stretch forming, a suitably shaped blank of sheet metal is drawn or formed into a die cavity to produce a part. A clamping ring, draw beads, and/or other restraints are usually applied at the periphery of the blank to prevent wrinkling and/or tearing of the blank as it is drawn or formed into the die cavity. The complexity of the required restraint at the periphery of the blank is usually directly proportional to the complexity of the formed part.

A deep-drawn part is characterized by having a depth greater than the minimum part width. A deep-drawn part can be fabricated in a single

drawing step or in multiple steps by redrawing preforms developed by deep-draw, shallow-draw, and/or stretch-forming methods. Ironing can be used during redrawing to control the wall thickness of the final part. Additional anneals may be required between redrawing steps. Successful deep drawing is highly dependent on the control of the frictional forces between the tools and the metal. The friction between the metal and the holddown pad and between the metal and the punch provides the tension that draws the metal to the deep-drawn or stretch-formed shape. The gradual and uniform release of the metal under the holddown pad allows it to flow into the die without developing wrinkles and puckers. The thickness of the metal, clearance between tools, condition of the metal surfaces, and lubrication all help to determine how high and how uniform the frictional forces will be (Ref 3).

A shallow-drawn part has a depth less than the minimum part width and is usually formed in one process step. It can be a final part or the preform for deep drawing.

A stretch-formed part is fabricated by pressing a punch into a blank that is fully or partially restrained at its periphery to develop positive biaxial strain on the part surface. A stretch-formed part can be a final part or the preform for drawing operations. Additional information on drawing and stretch forming is available in the articles "Deep Drawing" and "Stretch Forming" in this Volume.

## Materials Characteristics and Effects of Alloy Composition and Temper

**Single-Step Drawing.** Copper alloys that have high  $r$  values will provide the largest limiting draw ratio in a single deep-draw step. The  $r$  value is defined as the ratio of true width strain to true thickness strain in the region of uniform uniaxial elongation during a tensile test. It measures the resistance of a material to thinning. The  $r$  value correlates with deep-drawing performance because it reflects the difference between the load-carrying capability of the cup sidewall and the load required to draw in the flange of the cup or blank during a deep-drawing operation.

The deepest single-step draws (highest LDR) can be made with alloy C52100, followed by the brasses (in order of decreasing zinc level) and by copper. The LDR of cartridge brass (alloy C26000) increases as its grain size increases.

**Multiple-Step Deep Drawing.** The number of redrawing steps and the frequency of intermediate annealing treatments depend on the initial preform geometry, the extent of ironing required, and the work-hardening rate of the particular alloy. Fewer redrawing steps are required if the preform geometry closely matches that of the final part. The trade-offs involved in selecting a fabrication procedure for the initial preform (for example, deep drawing, shallow drawing, or stretch forming) are complex.

In contrast to single-step deep drawing, in which alloys with high work-hardening rates give the highest LDR, copper alloys with lower work-hardening rates can be redrawn and ironed to larger height/diameter ratios (a higher number of deep-draw steps) without intermediate annealing. The curves shown in Fig. 15 suggest that alloy C11000 (electrolytic tough pitch copper) will possess better redrawing and ironing characteristics and will require lower press forces than copper alloys with solute additions of zinc, tin, and/or silicon.

In general, the reduction at each redrawing step is successively decreased to ensure that the punch forces required to decrease the flange circumference do not exceed the load-carrying capability of the part sidewall. The magnitude of the incremental steps of redrawing is decreased if the part sidewall is to be ironed. Ironing increases the strength of the sidewall and flange proportionally to the distance from the cup bottom. In some applications, redrawing capacity can be improved by increasing the temper of the initial strip to enhance the load-carrying capability at the junction of the part sidewall and the cup bottom. The alternative is to use an alloy with a lower work-hardening behavior (Fig. 9 to 11) or an alloy with a higher  $r$  value.

**Stretch Forming.** The stretch formability of copper alloys correlates with the total elongation measured in a tension test. Annealed alloys that show high work-hardening rates offer the best stretch-forming characteristics. Improved combinations of strength and stretch formability are achieved by solute elements that greatly increase the work-hardening rate. Cold rolling to increase strip temper (strength) significantly reduces stretch formability.

The variation of tensile elongation with cold rolling reduction for copper alloys is shown in Fig. 16. These data indicate that high-tin and high-zinc alloys offer the best combinations of strength and stretch formability.

**Specific Characteristics of Copper Alloys.** The higher-zinc brasses, such as alloy C24000 (low brass), alloy C26000 (cartridge brass), and alloy C26200 (high brass), have strengths comparable to those of low-carbon steels. They are outstanding materials for deep drawing and stretch forming.

Many other families of copper alloys also have good deep-drawing and stretch-forming properties. Phosphor bronze A (alloy C51000) has an excellent combination of high strength and high ductility and is used to form deep-drawn thin-wall shells that are then annealed and corrugated

to produce bellows with high fatigue strength, corrosion resistance, and excellent flexibility.

The nickel silvers (copper-nickel-zinc) are copper alloys with a white or gray color that also have excellent deep-drawing characteristics similar to those of the high-zinc brasses. However, they have somewhat higher work-hardening rates and require more frequent anneal treatments during redrawing when compared to

**Fig. 13** Bend formability of copper alloys as a function of rolling direction. Bends with the axis transverse to the rolling direction are termed good-way bends; bends with the axis parallel to the rolling direction are bad-way bends. See also Table 7. Source: Ref 3

**Fig. 14** Impact of bend anisotropy on part layout. (a) Hypothetical part, which has equal-radius bends at 90° orientations in the plane of the strip. Selection of the appropriate copper strip alloy for this application depends on the material strength and the bend properties in the relevant orientations. (b) Potential nesting of blanks for the part shown in (a). Layout A is required for directional alloys such as C51000 and results in 38% scrap; a non-directional alloy such as C68800 would allow the more efficient layout B, with 23% scrap. Dimensions given in millimeters (1 in. = 25.4 mm). Source: Ref 3

cartridge brass. In the fully annealed condition, alloy C63800 (Cu-3Al-2Si-0.4Co) also exhibits good deep drawability (similar to that of the

nickel silvers). Annealed high-zinc leaded brasses are suitable for shallow-drawn parts, such as garden-hose coupling nuts.

**Fig. 15** Redrawing characteristics of 1.0 mm (0.040 in.) thick sheets of several copper alloys. Curves of lower slope indicate a lower rate of work hardening and therefore a higher capacity for redrawing. Source: Ref 3

**Fig. 16** Stretch-forming characteristics of 1.0 mm (0.040 in.) thick copper alloys. Elongation values for a given percentage of cold reduction indicate the remaining capacity for stretch forming in a single operation. Source: Ref 3

Copper-zinc-tin alloys such as C40500, C41100, C42200, and C425000 respond well to drawing and redrawing operations. With regard to deep-drawing properties, C40500 and C41100 are similar to the high-copper brasses, and C42200 and C42500 are similar to C24000.

Beryllium coppers can be drawn in the solution-annealed temper and then age hardened. For example, annealed alloy C17200 has been deep drawn to 80% reduction before annealing. Parts drawn from beryllium-copper alloys can subsequently be heat treated to produce tensile strengths to 1275 to 1380 MPa (185 to 200 ksi). Beryllium-copper alloys are often used in parts that require high strength and high fatigue performance, for example, bellows applications.

There are many other special-purpose coppers and copper alloys. By examining their compositions and mechanical properties carefully and by comparing them with standard alloys, the user can estimate how they will respond in deep-drawing applications.

**Grain Size Effects.** For the coppers and single-phase alloys in annealed or light cold-rolled tempers, grain size is the basic criterion by which deep drawability and stretch forming are measured. In general, for a given alloy and sheet thickness, ductility increases with grain size, and strength decreases. However, when grain size is so large that there are only a few grains through the thickness of the sheet or strip, both ductility and strength, as measured by tensile testing, decrease. Figure 17 illustrates how elongation changes with grain size for three different thicknesses of alloy C26000 (cartridge brass). General recommendations for the grain size of annealed strip for drawing and stretch-forming operations are provided in Table 8, along with the expected surface characteristics.

For optimal deep-drawing and stretch-forming properties, the grain size chosen should provide maximum elongation. With reference to Fig. 17, peak elongation for 0.15 mm (0.006 in.) thick

**Fig. 17** Elongation versus grain size for alloy C26000 sheets of various thicknesses. Source: Ref 3

strip occurs at an average grain size of 0.020 mm (0.0008 in.). For 0.40 mm (0.0157 in.) thick brass, a range of 0.038 to 0.061 mm (0.0015 to 0.0024 in.) average grain size would provide maximum drawability. For 0.81 mm (0.032 in.) thick material, a range of 0.060 to 0.090 mm (0.0024 to 0.0035 in.) average grain size would give optimal performance.

The surface finish required on the final part is an important consideration when selecting the grain size to be used. When metal with a coarse grain size is drawn or stretch formed, the surface roughens and develops an appearance resembling orange peel. Such a surface is more difficult and costly to polish and buff. Therefore, when a part has a buffed surface requirement, much effort is often expended to design tools and fabrication sequences that allow the use of brass strip with a fine grain size.

A classic example of this situation is the one-piece brass or bronze doorknob (Fig. 3a). Such useful and decorative articles are made by the millions, and these types of shapes are difficult to produce on draw presses. These parts are usually produced in transfer presses, and the process can include 15 to 20 operations with one intermediate anneal or partial anneal. The alloy C26000 or C22000 strip from which these parts are made is usually approximately 0.76 mm (0.030 in.) thick, and the grain size is usually 0.020 to 0.035 mm (0.0008 to 0.0014 in.) or 0.015 to 0.030 mm (0.0006 to 0.0012 in.) to provide sufficient ductility for the part to be drawn without surface roughening.

**Friction Effects (Ref 3).** Each copper alloy has inherently different coefficients of friction against tool steels. For example, the coefficient of friction of copper against tool steels is higher than that of brass. The high-zinc brasses have coefficients of friction lower than the copper-rich brasses, and these values vary with zinc content. The phosphor bronzes have high coefficients of friction when compared to high-zinc brasses. The nickel silvers have higher friction coefficients than brasses, and cupro-nickels higher

values than the nickel silvers. These general guidelines regarding friction coefficients are from experience; actual values are dependent on tooling, lubricant, strip characteristics (gage, gage tolerance, tensile properties, etc.) and the deep-draw part geometry.

Other material factors that can directly influence deep-draw characteristics are surface topography produced by cold rolling, surface cleanliness (annealing atmospheres and/or cleaning practices during strip processing), mechanical surface damage (scratches, rolled-in defects, flakes, etc.), residual fluids from cold rolling or slitting, and/or moisture stains from shipping or storage.

**Special Considerations (Ref 4).** A common concern in all drawing operations is the formation of ears at the top of the cup sidewall. Ears occur in preferred directions (usually 45° or 0° and 90°) relative to the strip-rolling direction and indicate a difference in the cup sidewall thickness (thinner in earring orientations and thicker in valley orientations) in parts deep drawn or redrawn without ironing. Earring reflects the crystallographic texture of the strip. In part manufacture, parts with ears may be difficult to transfer station-to-station in stamping presses. The ears trimmed from finished parts represent excess scrap, and parts with ears will have varying sidewall thickness. Accordingly, non-earring grades of copper and copper alloy strip are almost always specified for drawn parts.

For copper alloys, the reduction in diameter in a single draw (cupping) usually ranges from 35 to 50%, with a 50% reduction corresponding to ideal conditions. Drawing procedures vary widely in commercial practice. Reductions for successive draws of the commonly formed brasses, under favorable operating conditions and without intermediate annealing, are usually 45% for cupping; 25% for the first redraw; and 20, 16, 13, and 10% for subsequent redraws. Greater reductions are usually obtained with blank thicknesses greater than approximately 1.62 mm (0.064 in.); for blank thicknesses

less than approximately 0.38 mm (0.015 in.), reductions are usually approximately 80% of the percentages given previously. With an annealing operation before each redraw, a reduction of 35 to 45% in each successive redraw can be obtained under favorable operating conditions, assuming that the accompanying reduction in wall thickness is acceptable.

Die radius usually varies from approximately 20 times the metal thickness for material 0.127 mm (0.005 in.) thick to approximately 5 times the metal thickness for material 3.18 mm (0.125 in.) thick. Radii of this size prevent high stress concentrations at the die opening, which can lead to tearing in subsequent draws. Sharper radii are needed for flanged shells and for meeting special design requirements.

The nose radius of the punch, except for the final stages of drawing, is usually less than one-third of the punch diameter, or four to ten times the metal thickness. Clearance between punch and die is usually maintained at values to produce a slight amount of ironing of the sidewalls.

## Coining

**Nature of the Operation.** Coining is a cold forming process in which the work metal is compressed between two dies to fill the depression of both dies in relief or to reduce the strip thickness. The most familiar coining operation is the minting of coins. However, one of the most common uses of coining is in reducing the thickness or width of localized regions of electrical and electronic connectors and leadframe leads.

**Materials Characteristics.** The ability of a material to be coined is determined by its strength and work-hardening rate. In general, copper, the lower-zinc brasses, the lower-alloy nickel silvers, and the copper nickels, which all exhibit low work-hardening rates, exhibit good coinability (Fig. 15).

## Spinning

**Nature of the Operation.** Spinning is a method of forming sheet metal or tubing into seamless hollow cylinders, cones, hemispheres, or other circular shapes by a combination of rotation and force. Manual and power-automated equipment is used for spinning copper alloys. More information is available in the article "Spinning" in this Volume.

**Materials Characteristics.** The principal materials factors that determine the spinnability of copper alloys are plastic-strain ratio ( $r$ ), total available elongation, and work-hardening rate. In general, alloys with high  $r$  values, high tensile elongation, and low work-hardening rates exhibit the highest spinnability.

**Effects of Alloy Composition and Temper.** Tough pitch copper (alloy C11000) is the easiest copper material to spin and usually does not require intermediate annealing. Brasses, except

**Table 8 Available grain size ranges and recommended applications**

Average grain size		Type of operation and surface characteristics
mm	in.	
0.005–0.015	0.0002–0.0006	Shallow forming or stamping. Parts will have good strength and very smooth surface. Also used for very thin metal
0.010–0.025	0.0004–0.001	Stampings and shallow-drawn parts. Parts will have high strength and smooth surface. General use for metal thinner than 0.25 mm (0.010 in.)
0.015–0.030	0.0006–0.0012	Shallow-drawn parts, stampings, and deep-drawn parts that require buffable surfaces. General use for thicknesses under 0.3 mm (0.012 in.)
0.020–0.035	0.0008–0.0014	This grain size range includes the largest average grain that will produce parts essentially free of orange peel. Therefore, it is used for all types of drawn parts produced from brass up to 0.8 mm (0.032 in.) thick.
0.010–0.040	0.0004–0.0016	Begins to show some roughening of the surface when severely stretched. Good deep-drawing quality in 0.4–0.5 mm (0.015–0.020 in.) thickness range
0.030–0.050	0.0012–0.002	Drawn parts from 0.4–0.64 mm (0.015–0.025 in.) thick brass requiring relatively good surface, or stamped parts requiring no polishing or buffing
0.040–0.060	0.0016–0.0024	Commonly used for general applications for the deep and shallow drawing of parts from brass in 0.5–1.0 mm (0.020–0.040 in.) thicknesses. Moderate orange peel may develop on drawn surfaces.
0.050–0.119	0.002–0.0047	Large average grain sizes are used for the deep drawing of difficult shapes or deep-drawing parts for gages 1.0 mm (0.040 in.) and thicker. Drawn parts will have rough surfaces with orange peel except where smoothed by ironing.

for the multiphase alloy Muntz metal (C28000), are readily spun, although the higher-zinc brasses sometimes require intermediate annealing. Tin brasses containing at least 87% Cu require higher spinning pressure and more frequent annealing than brasses. Nickel silvers that contain at least 65% Cu, as well as the copper nickels, are also well suited for spinning. Phosphor bronzes, aluminum bronzes, and silicon bronzes are difficult to spin but can be spun into shallow shapes under favorable conditions. Copper alloys that are difficult to spin include Muntz metal, nickel silvers containing 55% Cu or less, beryllium coppers, alloys containing more than approximately 0.5% Pb, naval brass (C46400), and other multiphase alloys.

The single-phase high-strength copper alloys can be heated for spinning to reduce the force required to permit the spinning of thicker material or to permit more severe deformation, provided the increased cost for heating is justified. The forming characteristics of Muntz metal, extra-high-leaded brass, and naval brass are also improved at elevated temperature, but special precautions must be taken to avoid even the unintentional heating of the workpiece in spinning brasses that contain 0.5% Pb or more and more than 64% Cu.

Annealed tempers are almost always used in spinning copper alloys. Larger grain sizes (lower hardnesses) are easier to spin; finer grain sizes may be needed to meet surface finish requirements.

Although stock as thin as 0.1 mm (0.004 in.) can be manually spun under special conditions, manual spinning is usually restricted to thicknesses of 0.51 to 6.35 mm (0.020 to 0.250 in.). Powered equipment is used in the upper part of this range, and stock thicknesses in excess of 25 mm (1 in.) can be shaped by hot power spinning.

**Applications.** Typical products that are spun from copper alloys include bell-mouth shapes for musical instruments, lighting fixture components, vases, tumblers, decorative articles, pressure vessel parts, and other circular parts with bulged or recessed contours.

## Contour Roll Forming

**Nature of the Operation.** Contour roll forming is an automated high-speed production process that is capable of producing tubular, box, angular, and folded parts of varied and complex shapes (see the article "Contour Roll Forming" in this Volume). Auxiliary operations such as notching, slotting, punching, and embossing can be combined with contour roll forming.

**The materials characteristics** that determine the roll-forming capability of copper alloy strip are the same as those that govern bend and stretch formability (see the sections "Bending" and "Drawing and Stretch Forming" in this article).

**Alloy and Temper Effects.** The bend properties given in Table 7 provide an indication of

the relative suitability of copper alloys for contour roll forming. Annealed tempers are needed for complicated shapes and parts with extremely sharp bends or for severe stretch forming.

**Applications.** Contour roll forming is used less extensively with copper alloys than with steel and aluminum alloys because there are fewer copper alloy parts that are made in sufficient volume to be produced economically by this type of forming operation. Applications are primarily in the automotive and architectural industries.

## Rubber-Pad Forming

**Nature of the Operation.** In this process, the rubber pad usually serves as the female die, in conjunction with an inexpensive male punch. The pad is practically incompressible, and it transmits pressure in all directions in the same manner as hydraulic fluid. Rubber-diaphragm forming uses hydraulic fluid behind the rubber pad. The most important reasons for using rubber-pad forming in preference to conventional press techniques or other production methods are improved formability, low tooling costs, and freedom from marking of workpiece surfaces. This is the most cost-effective method of fabricating one-piece doorknobs.

Deep drawing by rubber-diaphragm or Marforming techniques often permits a 65% reduction of diameter in a single draw, without producing wrinkles or surface defects that could require expensive finishing operations. More information on the Marform process and other rubber-pad forming techniques is available in the article "Rubber-Pad Forming and Hydroforming" in this Volume.

**Materials Characteristics.** The materials properties of greatest importance in rubber-pad forming are the same as those that control strip performance in metal dies; that is, deep drawing is dependent on the plastic-strain ratio ( $r$ ), stretch forming is dependent on tensile elongation, bending is determined by strip ductility, and so on.

**Effects of Alloy Composition and Temper.** The same principles can be used to select the appropriate alloy composition and temper for rubber-pad die forming that are used for parts formed with conventional metal dies.

## Specialized Forming Operations

**Hydraulic Forming.** Copper alloys are sometimes formed by applying direct hydraulic pressure to the surface of the workpiece in order to shape the workpiece against a rigid die. This procedure can be used to form grooves on large, thin, flat sheets and to shape small parts to irregular contours. Tool cost is low, but the method is ordinarily applicable only to small-lot production because of comparatively low production rates.

**Embossing and swaging,** which are closely related to coining (being compressive or defor-

mation operations), are also frequently used in the cold forming of copper alloys. The principles of alloy selection described for coining apply equally to embossing and swaging. However, embossing (impressing letters, numerals, or designs into a surface by displacing metal to either side) can be done on any copper alloy, with special attention to tooling and selection of temper on the less formable alloys. Swaging is often used for the production of complicated electrical contacts from copper or brass.

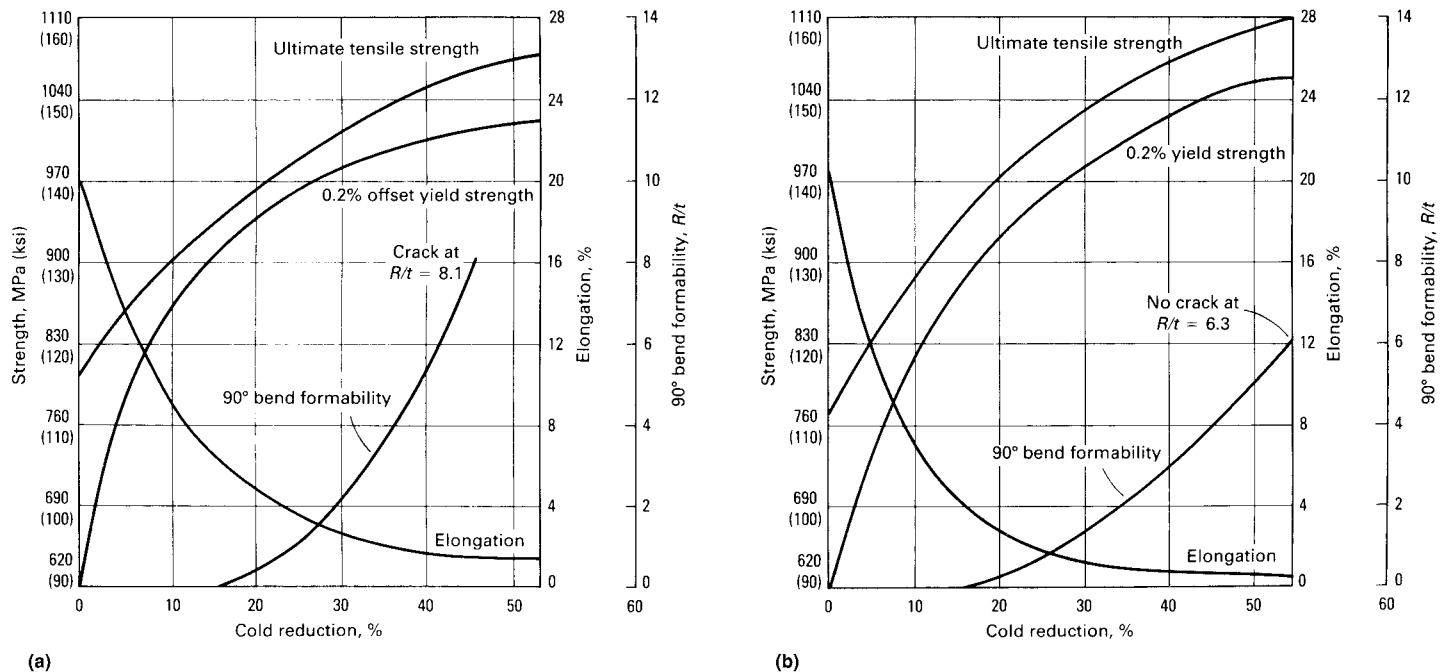

**High-velocity metal forming,** also known as electromagnetic forming or magnetic pulse forming, is a process for forming metal by the direct application of an intense, transient magnetic field. The workpiece is formed without mechanical contact by the passage of a pulse of electric current through a forming coil (see the article "High-Velocity Metal Forming" in this Volume).

Electromagnetic forming can be used on copper and some brasses because of their high electrical conductivity and excellent formability. Metals with a resistivity greater than approximately  $16 \text{ m}\Omega \cdot \text{cm}$  are formed by the use of a copper or aluminum electromagnetic driver that is one to three times the thickness of the work metal. Thermally or electrically conductive joints and structural joints are produced in a single forming operation. Field shapers are frequently used to concentrate the forming force.

Electrical connections are made by electromagnetically swaging a copper band onto the end of stranded electrical conductor wire before insertion into a brass terminal. Optimal conductivity with 100% mechanical strength and long life under severe service conditions are obtained by using swaging forces great enough to compact the strands of the conductor so that a cross section of the joint appears to be essentially solid copper.

**Special Forming Considerations for Conductive Spring Materials.** Increasingly, contact designers are developing parts that rely on stepped or tapered beam thickness for optimal deflection or normal force characteristics. Some designs involve complex geometries requiring high formability in some regions (as for crimp connections) coupled with high strength in other regions (to resist permanent set in spring connections). Stepped or tapered contact beam thicknesses can be achieved by coining heavier-gage strip in progressive dies. This practice, however, rapidly work hardens copper alloys and reduces their formability. Die progressions that include the forming of contacts after a coining operation must incorporate more generous minimum bend radii than those suggested in the product literature of the supplier.

Figure 18 shows this change in formability for a mill-hardened temper of alloy C17200 that was subjected to coining up to 50% reduction in area and simulated by cold rolling after mill hardening. To avoid this formability problem, strip can be purchased with variable gage across the slit width, which is produced by profile milling or skiving or by the longitudinal electron beam

**Fig. 18** Change in formability as a function of the coining of alloy C17200 in (a) longitudinal and (b) transverse directions. The effect of coining is simulated by cold reduction. Original strip thickness in both cases was 0.41 mm (0.016 in.). Bend formability is measured as the ratio of bend radius ( $R$ ) to strip thickness ( $t$ )

welding of dissimilar thicknesses of strip. The need for localized high formability can also be met by the longitudinal electron beam welding of dissimilar metals, combining, for example, ductile C19500 with high-strength mill-hardened C17200.

An emerging electron beam application is the localized thermal softening of mill-hardened copper alloy strip to provide increased formability with no sacrifice in strength in the remainder of a contact. Examples of these unique copper alloy strip forms are shown in Fig. 19.

**Fig. 19** Special treatment of copper alloy strip for optimized combinations of formability and spring characteristics. (a) Profile milled strip. (b) Dissimilar thicknesses longitudinally welded; this method can also be used to join dissimilar alloys. (c) Localized heat treatment (electron beam softening)

## Springback

Springback is the elastic recovery that occurs in a plastically deformed part when it is released from tooling. It causes the final part to have a geometry different from that of the press tooling. The springback that occurs in a bending operation is shown schematically in Fig. 20. Springback must be taken into account in design of tooling and materials selection.

Springback depends on alloy, temper, thickness, bend radius, and the angle of bend. For fixed tooling and press conditions, springback increases as the strength of the copper alloy strip

increases. Therefore, springback is increased by cold rolling to increase strip temper and/or by alloy additions that increase strength. The springback behavior of three copper alloys (C21000, C26000, and C35300) is shown in Fig. 21. These data indicate that springback increases with increasing bend radius and decreasing strip gage. Springback values for tempers or bend radii not shown can be interpolated from Fig. 21. Some strip suppliers will provide springback data for selective copper alloys on request.

Three techniques are commonly used to compensate for springback: overbending, restriking, and the use of special dies. Overbending simply deforms the part to a larger bend angle so that it is at the desired value after springback. Restriking in original dies reduces springback in much the same manner as overbending, that is, by the introduction of additional plastic deformation. Special dies often use coining action at bend radii to deform the metal plastically in the bend area beyond the elastic limit. In other die modifications, the metal is pinched slightly at the bend region. When special dies are used, careful control must be exercised because excessive thinning can cause part failure during bending or can make the part susceptible to early failure in service.

**Fig. 20** Schematic of springback in a bending operation.  $t$  is sheet thickness,  $R_0$  and  $\alpha_0$  are the die radius and bend angle, and  $R_f$  and  $\alpha_f$  are the part radius and bend angle after springback.

## Forming of Larger Parts from Copper and Copper Alloy Strips

Forming limit analysis provides the means to assess sheet metal formability over a wide range

of forming conditions, including drawing, bending, and stretching. The amount of deformation that occurs during sheet forming, that is, the strain state, is given in terms of, or related to, major and minor strains ( $\epsilon_1$  and  $\epsilon_2$ , respectively) measured from fiducial markings (typically contacting circles with 2.5 mm, or 0.1 in., diameters) printed or etched onto strip surfaces prior to fabrication. The analysis requires two curves:

- A forming limit curve (FLC), which indicates the ability of the material to distribute localized strain
- A limiting dome height (LDH) curve, which indicates the overall ductility for forming of the material

These empirically determined curves show the biaxial strain or deformation limits beyond which failure may occur in sheet metal forming. More information on the development and use of these curves is available in the article "Formability Testing of Sheet Metals" in this Volume.

Forming limit and limiting dome height curves for 13 copper alloys are shown in Fig. 22 and 23. Table 9 lists UNS designations, common names, alloy compositions, and tempers for the alloys tested. These data indicate that, in annealed tempers, high-copper and copper-zinc alloys exhibit the highest FLC values, followed closely by alloys C72500, C51000, and C74300; these materials in turn are slightly better than alloys C19400, C75200, and C70600. Increasing the temper by cold rolling decreases forming capability, as shown in Fig. 22. The LDH data essentially follow the trend shown in FLC behavior.

**Solving Forming Problems.** In addition to displaying the relative formability of one material versus that of another, FLCs and LDH curves are valuable for identifying the cause of a sudden production problem that may arise from changes in tooling, lubrication, or material suppliers. This permits the forming process to be modified to maximize formability and productivity.

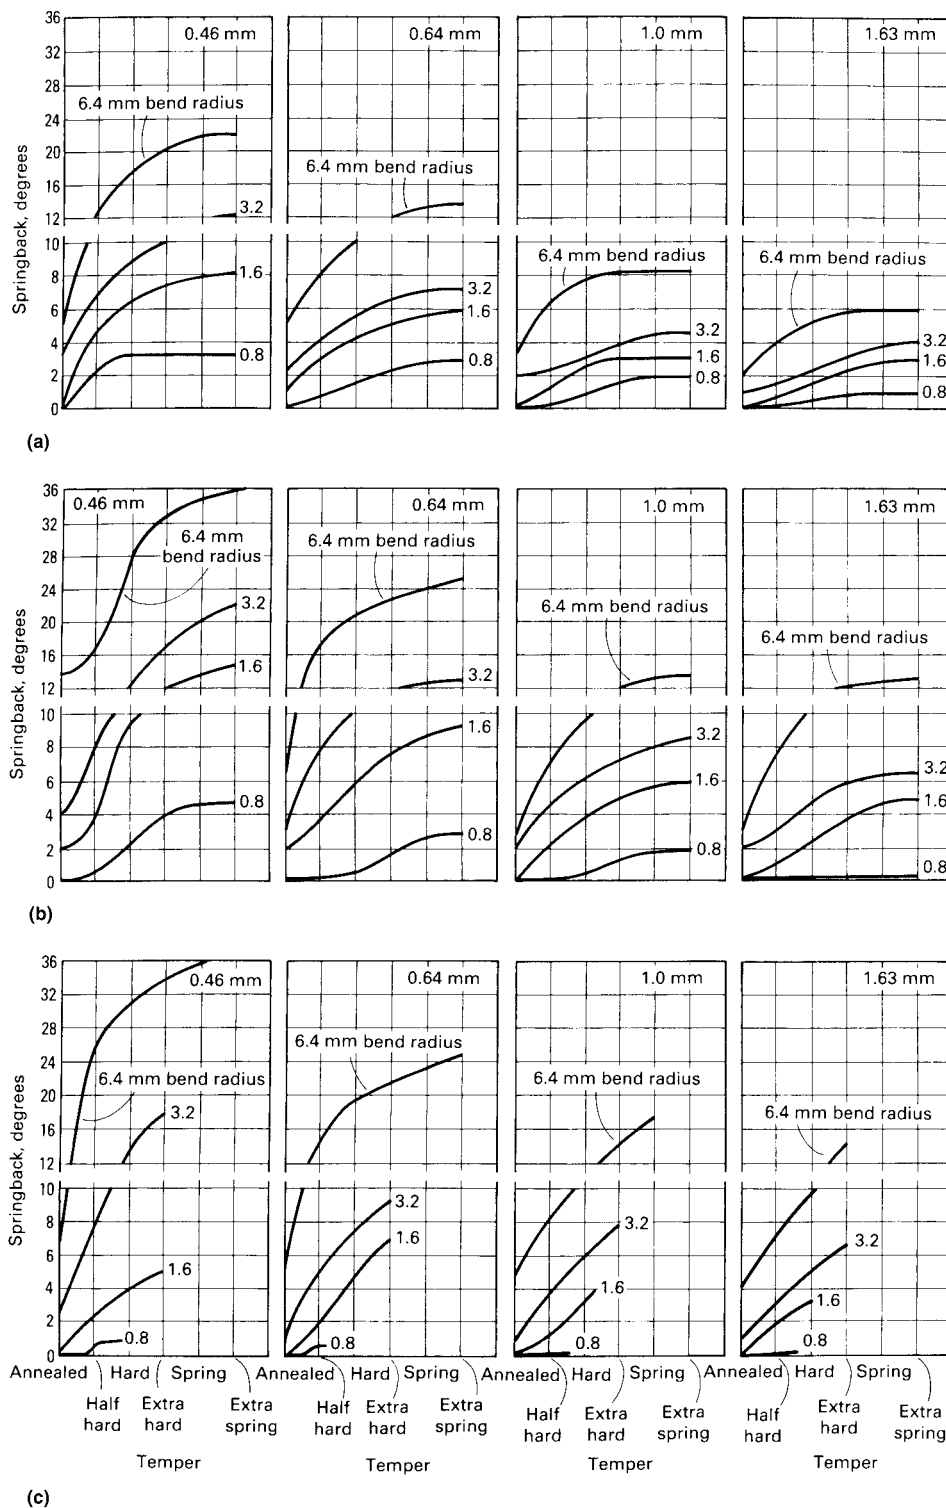

The most direct approach for determining the cause for an unexpected forming problem is to compare the LDH curve of the suspect lot with that of the control lot of known good material. If only one region of the part is subject to critical strains, it may be necessary only to test the blank width that will produce that critical value of minor strain. If the LDH curve of the new material is the same as that of the control lot, then tooling or lubrication is suspect. If the LDH curve of the new material is below that of the control lot, the material is the problem.

The best way to determine whether tooling or lubrication conditions have changed is to form a gridded sample under current tool conditions from a control lot held in inventory. Strain distribution and critical grid strains measured on this sample can be placed on the established FLC and compared with those before the problem arose in order to establish their relationship to known, safe strain levels. If changes are detected, they can often be remedied by adjusting press

conditions to change the magnitude of stretch or draw components.

This is illustrated in Fig. 24. Point A on this FLC represents the strains in the critical region of a part when the part was being formed satisfactorily. Point B represents the critical strains when

forming became a problem because the major and minor strains were too high. Draw beads, blank holddown pressure, blank size, and/or lubrication can be modified to change the amount of major and minor strains. The effects on critical strain can be compared on the FLC to ensure that

**Fig. 21** Springback behavior of copper alloys as a function of temper, sheet thickness, and bend radius (90° bends). (a) Alloy C21000. (b) Alloy C26000. (c) Alloy 35300

the adjustments will indeed enable the part to be formed.

A similar approach can be used to adjust the forming operation so that a less ductile material can be formed. Figure 25, for example, shows FLCs for two materials (A and B) and the critical strain combination (point X) measured on a formed part. Material A forms successfully, but material B fractures during forming, as indicated by the location of point X relative to the FLC of each material.

Because of the shape of the FLCs, it is possible to maintain approximately the same  $e_1$  value for point X but to fall in the safe region by changing  $e_2$ , as indicated by points X' and X''. In this case, moving toward X' requires that the draw component be increased during forming; moving toward X'' requires that the stretch component be increased. Either can be accomplished by altering lubrication, tooling, and/or blank holddown pressure, thus enabling the part to be formed in material B.

### Forming of Smaller Parts from Copper and Copper Alloy Strips (Ref 7–10)

With the recent advances in software, computing speed, and storage capacity, parts are often developed or designed by finite-element analysis (FEA) techniques. Simplistically, the FEA approach uses strip property data, the geometry of the part, and the boundary and loading conditions to calculate the strain and stress distributions of a formed part. By matching the

calculated strains to a material forming limit diagram (or a similar failure criterion), an assessment can be made as to whether the part can be formed from a specific copper alloy in a specific temper condition.

For larger parts, it is possible to experimentally verify (by fiducial grid measurement or by analytical calculation) that the strains calculated by FEA match the actual strain in the part. This verification is not possible for typical electronic terminals, connectors, leadframes, and/or bellows parts, which frequently have part dimensions that are less than the 2.5 mm (0.1 in.), or the plastic deformation in these parts is localized to regions that are less than the 2.5 mm (0.1 in.), the diameter of contacting circles typically used to measure forming strains in larger parts.

A measurement technology first published in the early 1990s that could address this shortfall is digital image correlation (DIC), a computer vision deformation mapping technique. This methodology can map local surface strains to an accuracy of approximately 0.05% when strip is plastically deformed in two dimensions (a tensile test or coining operation, for example) and approximately 0.5% when strip is deformed in three dimensions (a part with bends, stretch, draw, or redraw forming, for example). The minimum effective gage length over which strain and strain gradients can be measured is on the order of 0.05 mm (0.002 in.) (dependent on pixel density of the digital image and reference grid dimensions). The accuracy of the DIC method is sufficient to measure the diffuse and local necking strains during tensile testing of copper alloy strip in cold-rolled or precipitation-hardened tempers to verify the accuracy of

constitutive equations used in the FEA. This accuracy of strain measurement is also sufficient to verify whether FEA-calculated strains match actual strain values in formed parts. Cooperation is required between suppliers and users of copper alloy strips with high strength and moderate electrical conductivity to determine if application of DIC methodology can increase the accuracy of FEA to provide connector parts with improved performance.

### Property Requirements for Various Formed Products (Ref 11)

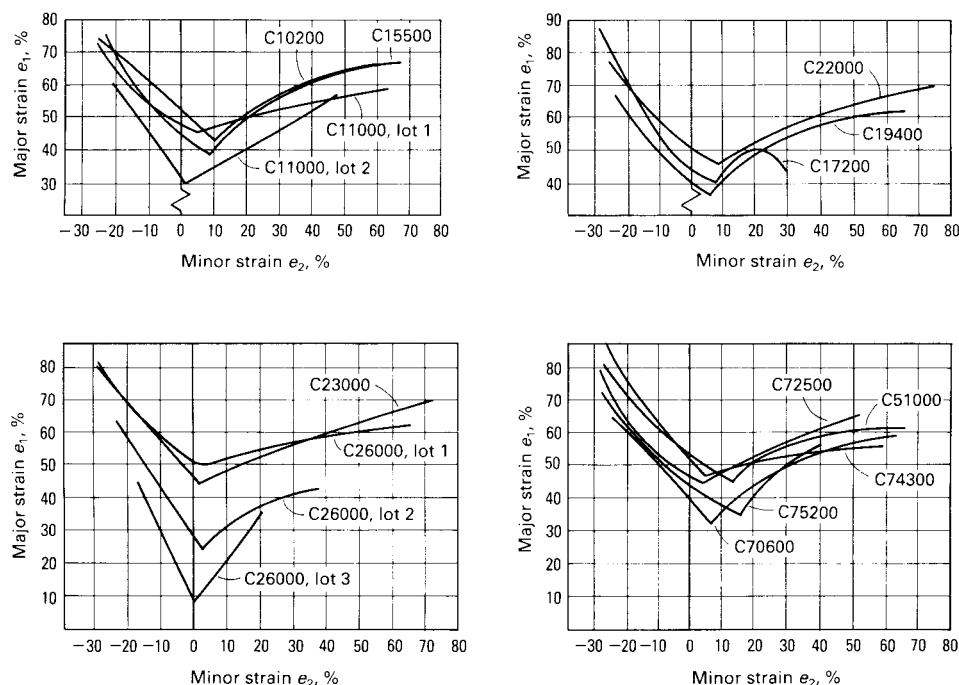

Because the selection of an alloy begins with performance requirements even before formability is considered, this section offers a brief discussion of alloy effects relative to the performance of copper alloys. When these factors are matched with the best formability considerations, optimal materials selection is attained.

**Electrical Conductors.** High conductivity is a primary requisite for many conductors, but not all conductors require high conductivity. Strength and resistance to creep or softening can be traded for some loss of conductivity. Thermal conductivity goes hand-in-hand with electrical conductivity and is usually required in all conductors operating in the high-amperage range.

**Terminals and connectors** are used in both electronic and electrical applications. Electrical circuits require greater current-carrying ability than electronic circuits, for which low-to-moderate conductivity will often suffice. Good formability at the required strength level, well-defined load deflection characteristics, and resistance to stress relaxation are usually required for both electrical and electronic connectors. Corrosion and stress-corrosion resistance and solderability are also often demanded.

**Other Electronic Applications.** The primary electronic application for copper and copper alloys, other than connectors and printed circuits, is as leadframes for semiconductor devices. Transistors, diodes, and integrated circuits can be fabricated on a semiconductor chip often less than 5 mm (0.2 in.) square. The chip is bonded to a substrate or leadframe, which serves both structurally and electrically to connect it to the outside world. Where copper alloys can be used, the materials requirements are expressed in terms of cost, conductivity, strength, softening resistance, formability, low-cycle fatigue resistance, and surface characteristics (such as plating, wire bonding, solderability, and plastic molding compound adherence).

**Hollow Ware, Flatware, and Decorative Applications.** The production of hollow ware products requires materials with good drawability. In addition, the material must have good solderability, corrosion resistance, sufficient strength to resist denting during manufacture or use, and good buffing and plating characteristics; most hollow ware products are silver or gold plated. The least expensive alloys that meet these

**Fig. 22** Forming limit curves (FLCs) for selected copper alloys. FLCs reveal local ductility during forming. See Table 9 for material designations, thicknesses, and tempers. Source: Ref 5, 6

criteria are the 10 to 30% Zn brasses. The lower zinc levels are used for multiple-redrawing applications, and the higher zinc levels are for parts demanding higher strength and/or deep-

drawing capability. Copper and phosphorus-deoxidized copper are significantly softer and are primarily used for decorative applications without plating, where the red color of the metal is

considered appealing. They have adequate drawability for parts that do not require side-wall ironing and a high work-hardening rate. Phosphorus-deoxidized copper is required where brazing is needed.

Flatware items are generally produced by roll forming. In addition to good formability, flatwork alloys must have good solderability, corrosion resistance, good buffing and plating characteristics, and low cost. Embossed items use annealed tempers of materials with sufficiently low work-hardening rates to give faithful reproduction of detailed patterns. Copper-zinc and copper-nickel-zinc alloys offer the required combination of properties; the zinc content is varied to suit the work hardening needed. A copper-nickel-zinc alloy that has a silvery color is generally used for silver-plated flatware, and Cu-30Zn is used for gold-plated flatware to minimize the color contrast between base metal and plate if damage to the plate occurs.

**Heat exchangers** require good thermal conductivity, corrosion and stress-corrosion resistance, joinability, and strength at modest cost. These requirements vary in importance for each application. Copper and copper alloys offer good combinations of these properties. The two major heat exchanger applications are steam condenser tubing and automotive radiators.

Condenser tubing must withstand potentially corrosive cooling water as well as the volatile components carried by the steam, which condense on the tubing. Corrosion requirements are paramount, but strength at elevated temperature and thermal conductivity are also required.

The copper alloys commonly used in power utility condensers include arsenic-, antimony-, or phosphorus-inhibited brasses; aluminum bronzes; or copper-nickels, depending on corrosion and stress-corrosion requirements. For automotive radiators, corrosion resistance, thermal conductivity, and fabricability are the primary requisites. Certain applications require strength at elevated temperature. Fabricability demands the ability to solder and to braise. Resistance to both atmospheric corrosion and corrosion by heat-transfer media and their decomposition products is required. Cooling fins are made of pure copper or high-copper copper alloys.

**Coinage.** General requirements include low cost, attractive appearance and high density for high denominations (to give the impression of intrinsic value), tarnish and corrosion resistance, modest strength, and ability to be coined easily. Specific additional requirements for vending machine use include control of conductivity, density, magnetic permeability, and eddy-current response. Apart from those few coins that are fabricated from stainless steel, most non-precious metal coins are made of copper alloys, which can meet these requirements.

**Ammunition.** The cartridge case that contains the explosive powder and primer for ammunition is made by a cup-and-draw process; a blanked disk is cupped, drawn to extend the sidewall, and redrawn for the same purpose. The drawing process is repeated until the wall is

**Fig. 23** Limiting dome height (LDH) curves for copper and copper alloys. LDH curves illustrate the overall ductility of the coppers and copper alloys evaluated. See Table 9 for material designations, thicknesses, and tempers. Source: Ref 5, 6

sufficiently thinned and extended. The case can be annealed between a series of draws to permit sufficient extension without cracking.

The primary materials requirements are related to fabricability, but stress-corrosion resistance and strength are also needed.

**Table 9 Coppers and copper alloys evaluated using forming limit analysis**

See Fig. 22 and 23 for results of analysis.

UNS designation	Common name	Material conditions applicable to forming limit curves and limiting dome height (LDH) curves
C10200	Oxygen-free copper	Annealed, 0.66 mm (0.026 in.) thick, 0.014 mm (0.0006 in.) grain, 234 MPa (34 ksi) UTS(a)
C11000, lot 1	Electrolytic tough pitch copper	Annealed, 0.74 mm (0.029 in.) thick, 0.016 mm (0.00063 in.) grain, 224 MPa (32.5 ksi) UTS(b)
C11000, lot 2	Electrolytic tough pitch copper	Half hard, 0.69 mm (0.027 in.) thick, 268 MPa (38.8 ksi) UTS, 20% tensile elongation(c)
C15500	Silver copper	Annealed, 0.71 mm (0.028 in.) thick, 0.009 mm (0.00035 in.) grain, 288 MPa (41.8 ksi) UTS
C17200	Beryllium copper	Annealed, 0.25 mm (0.010 in.) thick, 0.019 mm (0.00075 in.) grain, 491 MPa (71.2 ksi) UTS
C19400	HSM copper	Annealed, 0.69 mm (0.027 in.) thick, 319 MPa (46.3 ksi) UTS, 29% tensile elongation(d)

Cartridge brass (Cu-30Zn) is the most widely used copper alloy for shells and other ammunition; hence its name. Cartridge brass offers the best materials compromise for such applications, having excellent deep drawability, moderate redrawability, and sufficient strength. In press operations, its low coefficient of friction and absence of refractory oxides contribute toward low press forces, low tool maintenance, and good surfaces on the parts being formed. It is also low in cost. Formed cartridge cases must be stress-relief annealed to minimize the possibility of stress-corrosion cracking.

# Forming of Magnesium Alloys

E. Doege\*, B.-A. Behrens, G. Kurz, and O. Vogt, University of Hanover

MAGNESIUM ALLOYS are an important category of lightweight structural material with favorable specific strengths. For example, an important goal of the automotive industry is fuel efficiency, and one area of potential savings is weight reduction offered by magnesium alloy components, such as sheet metal body shell panels that are exposed to bending stresses (Ref 1). Currently, the weight of the car body is reduced by using high-strength steel with a decreased sheet thickness or conventional lightweight materials such as aluminum. In the future, aluminum and steel sheets may be replaced by magnesium sheets in some applications.

Currently, structural magnesium alloys are mainly processed by die casting in the automotive industry. Die casting technology allows the manufacture of parts with a complex geometry (Ref 2). The mechanical properties of these parts often do not meet the requirements concerning endurance, strength, ductility, and so on. A promising alternative for thin, large-surfaced parts, such as automotive body constructions, are components manufactured by sheet metal forming. In comparison to die-casted parts, sheet metal formed parts are characterized by advantageous mechanical properties and a good surface without pores. Therefore, the substitution of conventional sheet materials by magnesium sheets could lead to essential weight savings.

In terms of forming, magnesium alloys are much more workable at elevated temperatures due to their hexagonal crystal structures (as described in the following section, "Deformation Mechanisms of Magnesium," in this article). Magnesium alloys are usually formed at elevated temperatures, although some forming of magnesium alloys can be done at room temperature (see the section "Cold Forming" in this article). The methods and equipment used in forming magnesium alloys are the same as those commonly employed in forming other metals, except for differences in tooling and technique that are required when forming is done at elevated temperatures. Heat for manufacturing sheet metal components was first applied by the American aerospace industry. At first, cold-formed sheet metal parts were only finished by use of heated straightening machines. Afterward, heat was

applied during the forming process itself, using heatable tools and presses. Today (2006), deep drawing at elevated temperatures is only used in a few special applications.

## Deformation Mechanisms of Magnesium

Conventional magnesium alloys have a hexagonal lattice structure and possess a low formability at room temperature. Previous research projects thoroughly investigated the temperature-dependent processes in the lattice structure that increase the formability of magnesium alloys. The increase in plasticity that takes place in the temperature range from 200 to 225 °C (390 to 435 °F) has been described (Ref 3). The temperature at which plasticity increases depends on the metal alloy being used (Ref 3). The plasticity of pure magnesium increases at a temperature of 225 °C (435 °F). Studies report that slip happens basically in the basal plane of the hexagonal lattice structure at temperatures up to 225 °C (435 °F) (Fig. 1) (Ref 4–6).

Slip occurs in the direction in which the atoms are most closely packed. Another deformation mechanism occurring at room temperature is twinning. Twinning is a shear deformation process where parts of one crystal are reflected across a mirror plane. The mirror plane is called a twinning plane (Fig. 2). The main part of the twinning process happens in pyramidal planes (second-order type 1) (Fig. 3).

When the temperature exceeds 225 °C (435 °F), the mobility of atoms in the matrix increases as well, so that additional pyramidal slip planes are activated (Fig. 4). The additional slip planes cause a sudden increase in plastic deformation. In monocrystals, these slip systems are already activated at room temperature when the angle between crystal slip plane and stress direction is 6°, as demonstrated in Ref 7 and 8. Dislocation slip of prismatic planes is another forming mechanism of magnesium crystals (Ref 9). At low strain rates and a temperature of approximately 260 °C (500 °F), it is assumed that alternating slip of both pyramidal and prismatic slip planes leads to wavy slip bands on the material surface (Ref 10).

The Dow Chemical Company gives advice on the tool geometry of the MgAl3Zn1 (AZ31) magnesium alloy when this material is bent and deep drawn (Ref 11). Choosing large tool radii leads to slight deformations even at room temperature. Various authors state the minimum radii for bending magnesium sheets in a temperature range of 21 to 371 °C (70 to 700 °F).

**Fig. 1** Slip. (a) Slip plane in the hexagonal lattice structure. (b) Directions for the slip plane

\*Deceased

Allowable bend radii at room and elevated temperature from various sources are given in Tables 1 and 2 (Ref 12–14).

Fig. 2 Principle of twinning

Advice on tool radii for deep drawing rectangular components with a heated tool is given in Ref 12 (Table 3). The temperatures of the die

( $T_d$ ), the blankholder ( $T_{bh}$ ), and the punch ( $T_p$ ) are  $T_d = 316\text{ }^{\circ}\text{C}$  ( $600\text{ }^{\circ}\text{F}$ ),  $T_{bh} = 343\text{ }^{\circ}\text{C}$  ( $650\text{ }^{\circ}\text{F}$ ), and  $T_p = 232\text{ }^{\circ}\text{C}$  ( $450\text{ }^{\circ}\text{F}$ ). Punch edge radius values and die radius values also apply to deep drawing round components.

In order to avoid stress-corrosion cracking, cold-formed magnesium-aluminum-zinc alloy components and magnesium-thorium-manganese/zirconium alloy components need to be annealed after forming. Advice for choosing the anneal temperature and the necessary holding period is given in Ref 12.

Influences on Formability

Influence of Temperature on Flow Stress.

A key parameter in the forming of magnesium alloys is the forming temperature. Figure 5 displays the flow curves of the magnesium sheet material MgAl3Zn1 (AZ31) at different temperatures, determined in the uniaxial tensile test according to EN 10130 and EN 10002, part V. It is obvious that the stresses and possible strains depend strongly on the forming temperature. At higher temperatures, the flow stress decreases with increasing strain, because of the thermally activated work softening (Ref 15).

**Influence of Temperature on Deep Drawing.** Experiments with magnesium alloy MgAl3Zn1 (AZ31) at room temperature show that the ductility of the material is sufficient to form inner and outer flat vaulted car body parts. A partial heating could be used

in areas of higher true strains. At higher drawing ratios, deep drawing with process annealing or warm deep drawing should be used (Ref 16). For the production of parts at high true strains, it is necessary to heat the deep drawing process.

Figure 6 shows the results of deep drawing tests at different temperatures. These tests confirm the low formability of magnesium alloys at low temperatures and a good formability at elevated temperatures. The work-softening behavior of magnesium at higher temperatures, as shown in the uniaxial tensile tests, influences the heated deep drawing process, too. Consequently, the limit drawing ratio reaches a maximum in the temperature range from 200 to 250 °C (390 to 480 °F), which further activates the slip planes. Above this temperature level, the work-softening behavior of the material

prevails, and the limit drawing ratio decreases (Ref 15, 17).

**Influence of Temperature on Stretch Forming.** The manufacturing of flat vaulted parts is especially characterized by high loading under stretch forming conditions (biaxial tension). These stress combinations often result in a local fracture of the formed components, so that process modifications, for example, of the tool geometry and lubrication, become necessary.

The maximum stretching height ( $h_{\max}$ ) until fracture of the sheet material was used to evaluate the material behavior under stretch forming conditions. Figure 7 shows the values of  $h_{\max}$  that have been determined in stretch forming tests at three different temperatures (150, 200, and 250 °C, or 300, 390, and 480 °F). This figure shows that the maximum stretching heights of the magnesium alloys increase as temperature

**Fig. 5** Temperature-dependent flow curves of MgAl3Zn1 (AZ31) (initial sheet thickness,  $s_0 = 1.0$  mm, or 0.039 in.) determined in the uniaxial tensile test.  $\dot{\epsilon}$ , strain rate. Source: Ref 15

**Fig. 7** Maximum stretching height ( $h_{\max}$ ) for different sheet materials and temperatures.  $s_0$ , initial sheet thickness. Source: Ref 15

increases (Ref 15). Figure 8 shows a stretch-formed specimen.

**Influence of Strain Rate.** Figure 9 shows the influence of testing velocity on flow stress for the sheet material MgAl3Zn1 (AZ31) at a temperature of 200 °C (390 °F). Raising the elongation rate from  $\dot{\epsilon} = 0.004$  s<sup>-1</sup> (EN 10002) to  $\dot{\epsilon} = 3.0$  s<sup>-1</sup> leads to a considerable increase in flow stress. This effect is less significant if the experiments are carried out at lower temperatures. Furthermore, the tensile tests show that increasing velocity results in a lower maximum elongation of the material at any temperature (Ref 15).

The results gained by the tensile tests showed the significant influence of strain rate on the mechanical properties of magnesium alloys. Figure 10 displays the dependence of the limit drawing ratio on punch velocity during deep drawing at a temperature of 200 °C (390 °F). Due to the higher required stresses and the lower maximum strain at higher velocities, the limit drawing ratio shows a considerable decrease at higher punch velocities (Ref 15).

**Influence of Alloy Composition on Deep Drawing.** Forming properties are vitally

**Fig. 6** Temperature-dependent limit drawing ratio for MgAl3Zn1 (AZ31) and AlMg4.5Mn0.4 (AA5182). Source: Ref 15

**Fig. 8** Stretch-formed specimen. Material: MgAl3Zn1 (AZ31); initial sheet thickness,  $s_0 = 1.3$  mm (0.051 in.); forming temperature: 250 °C (480 °F). Source: Ref 15

important for producing magnesium sheet components. The limit drawing ratio ( $\beta_{0,max}$ ) can be used to assess formability under deep drawing conditions. Figure 11 shows the limit drawing ratio of MgAl2RE1 (AE21) at temperatures between 200 and 325 °C (390 and 620 °F). It can be seen that at 300 °C (570 °F),  $\beta_{0,max}$  is optimized ( $\beta_{0,max} = 2.2$ ) for this alloy. In contrast to the results of the tensile tests, the limit drawing ratio for MgZnREZr (ZEK100) at 225 °C (440 °F) is significantly higher ( $\beta_{0,max} = 3.0$ ) than for MgAl2RE1 (AE21) (Ref 18).

**Influence of As-Rolled Conditions on Flow Stress.** Figure 12 illustrates the flow curves of the magnesium sheet material AZ31 in different as-rolled conditions at room temperature and

at 200 °C (390 °F). The flow curves show the dependence of the stresses on the as-rolled conditions, especially at low temperatures. The influence on the flow stress decreases significantly at elevated temperatures (above 200 °C, or 390 °F). At room temperature, the curves demonstrate that the strain to failure of the rolled and heat treated sheet material is higher than the strain to failure of the sheet material under other as-rolled conditions. These results point out that the choice of the optimal as-rolled condition influences the formability of the magnesium sheet material, especially at low temperatures (Ref 19).

**Influence of As-Rolled Conditions on Deep Drawing.** Figure 13 displays the limit drawing

ratio of the magnesium alloy MgAl2RE1 (AE21) under different as-rolled conditions at a forming temperature of 300 °C (570 °F). The limit drawing ratio ( $\beta_{0,max}$ ) is 2.0 for the rolled, heat treated, and temper-rolled sheet in comparison to the rolled and heat treated sheet material ( $\beta_{0,max} = 2.2$ ). This result corresponds to the outcomes of the uniaxial tensile tests, where the heat treated and temper-rolled sheets showed higher flow stresses and lower strains in comparison to the rolled and heat treated sheet material (Ref 20).

## Cold Forming

Cold forming of magnesium alloys is restricted to mild deformation with a generous bend radius. Cylinders and cones can be formed from magnesium alloys at room temperature by using standard power rolls. Simple flanges can be press formed at room temperature. Table 2 (Ref 14) gives minimum radii for fast bending at room temperature, as in a press brake. Slightly smaller bend radii than those given in Table 2 may be used when forming speeds are slower, as in a hydraulic press or when proved by trial and error. Also, the minimum radius changes with the angle. Little or no change occurs as the angle becomes larger than 90°, but the radius decreases markedly as the angle becomes smaller than 90°.

**Surface Protection.** In low-production cold forming, a common method of preventing surface damage is to apply tape to critical areas of the work metal and, if feasible, to tool surfaces. It is especially important to keep the die clean and free from particles of foreign metal that can become embedded in the surface of the workpiece and impair its corrosion resistance.

Hard rubber inserts in dies are sometimes helpful in preventing damage to the work metal and in forming large radii. However, this practice is not recommended for high production, because the inserts wear rapidly and cause nonuniform workpieces.

**Reworking** of bends by straightening and rebending the same portion should not be done in cold forming, because of the possibility of failure.

**Springback** can be as much as 30° for a 90° bend in cold forming of magnesium alloys. The amount of springback increases as the angle of bend decreases and as the radius of bend curvature increases. Springback decreases as temperature is raised. The suggested springback allowances for right-angle bends in AZ31B sheet at room temperature are given in Table 4. Because springback is also affected by the materials being bent, the tooling used, bending speed, and dwell time, the correct amount of overbend (springback allowance) depends on the specific application. See the article “Springback” in this Volume for more details.

**Effect of Bending on Length.** Unlike aluminum alloys and steel, which lengthen in bending, magnesium alloys shorten, because the

**Fig. 9** Strain-rate-dependent flow curves of MgAl3Zn1 (AZ31) (initial sheet thickness,  $s_0 = 1.0$  mm, or 0.04 in.) determined in the uniaxial tensile test at a temperature of 200 °C (390 °F).  $\dot{\epsilon}$ , strain rate. Source: Ref 15

Fig. 12 As-rolled-dependent flow curves of MgAl3Zn1 (AZ31) (initial sheet thickness,  $s_0 = 1.0$  mm, or 0.039 in.) determined in the uniaxial tensile test at temperatures of 20 and 200 °C (70 and 390 °F).  $\dot{\epsilon}$ , strain rate

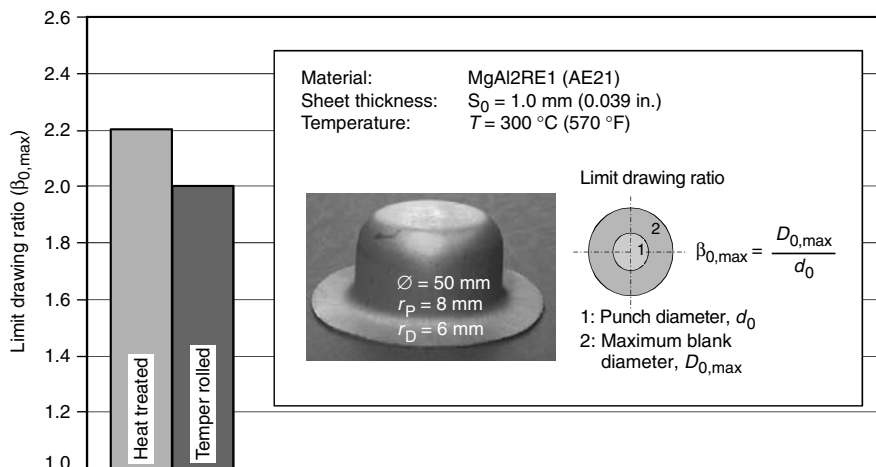

Fig. 13 Limit drawing ratios in dependence on as-rolled conditions.  $d_0 = 50$  mm (2 in.). Source: Ref 20

neutral axis moves slightly toward the tension side of the bend. For thin sheet, the extent of this shortening is small, because the axis shifts only 5 to 10%. However, in thicker sheet when several bends are made, the amount of shortening can be significant and must be allowed for in the development of the blank. A nomograph (Fig. 14) aids in this calculation.

**Stress Relieving.** Magnesium-aluminum-zinc (AZ) alloys should be stress relieved after cold forming to prevent stress corrosion. It may be desirable to stress relieve workpieces formed from the magnesium-thorium (HM, HK) alloys, particularly if they require straightening in fixtures. Recommended temperatures and times for stress relieving the magnesium alloys that are most commonly cold formed are given in Table 5.

## Hot Forming

The heating of the blank represents an additional process stage in sheet metal forming of magnesium alloys, which does not exist in the conventional sheet metal forming at room temperature. However, hot forming has several advantages over cold forming. Magnesium alloy parts usually are drawn at elevated temperature in one operation without repeated annealing and redrawing, thus reducing the time involved for making the part and also eliminating the necessity for additional die equipment for extra stages. Hardened dies are unnecessary for most types of forming. Hot-formed parts can be made to closer dimensional tolerances than can cold-formed parts because of less spring-back. Table 6 lists suggested maximum forming temperatures and times for various wrought magnesium alloys. The times given indicate the maximum time the alloy can be held at temperature without adversely affecting mechanical properties.

Table 4 Suggested springback allowances for right-angle bends (0.4–1.6 mm, or 0.016–0.064 in., thick sheet)

		5	1	1
		10	2	2
		15	4	4
290	550	Up to 15	0	0

Heating of the workpiece (or blank) can be done in an oven prior to placement in a die (Fig. 15, top), or the blank can be heated inside

the deep drawing tool as a result of heat conduction (Fig. 15, bottom). Heating equipment includes ovens, platen heaters, ring burners,

electric heating elements, heat-transfer liquids, induction heaters, and lamps and other types of infrared heating (see the section "Heating Methods" in this article). For small lots, tools and work may be heated by hand torches. Small dies that can be handled rapidly can be heated in ovens adjacent to the forming equipment.

External heating of the blank in an oven guarantees homogeneous blank temperature, but the disadvantage is a loss of temperature during transportation from the oven to the tool. For industrial processes, an automated transportation system with insulated boxes could be applied (Ref 21). When heating the blank inside the tool, the blank must be clamped between the blankholder and the die for a short time before drawing. Investigations show that only a few seconds of flat contact between the blank and the die are required for heating the blank to temperatures of approximately 200 °C (390 °F), due to the high coefficient of thermal conduction and the low heat capacity of magnesium alloys.

An advantage of heating inside the tool is the opportunity to achieve an optimized temperature distribution over the blank area by choosing different temperatures in individual tool areas. Experimental results showed that the limit drawing ratio of magnesium sheet can be increased significantly if the punch has a lower temperature than the die and the blankholder. In order to maintain constant temperature conditions, additional cooling of the punch could be necessary (Ref 22). Similar results have been achieved for the deep drawing of aluminum sheets at elevated temperatures (Ref 23, 24).

Another possibility for carrying out the deep drawing process at higher temperatures is the forming of an externally heated blank in an unheated tool. However, exact forming temperatures cannot be guaranteed in this case, due to the rapid heat transmission from the blank into the tool. For deep drawing of magnesium sheets, this process variant cannot be recommended because of the strong dependence of forming performance on temperature (Ref 25). In most hot forming methods, both the tools and the magnesium alloy work metal must be heated.

(a) If material is deformed below the minimum temperature shown, stress relief may be required.

Figure 16 shows the principal design of a deep drawing tool for use at elevated temperatures (Ref 26). Today (2006), deep drawing at elevated

temperatures is only used in a few special applications. Therefore, the knowledge of tool and process design is limited.

### Evaluation of Hot Forming Conditions

**Evaluation of Appropriate Heating Methods for Deep Drawing Tools.** Appropriate heating methods for deep drawing tools have been determined. Heating of tools can be achieved by means of resistance heating, induction heating, and heating with fluid. To determine the best solution, the three methods were evaluated according to the criteria of transferable heat quantity, control accuracy, thermal efficiency, and initial and operational costs. Table 7 shows that resistance heating provides the best solution to heat deep drawing tools, from a thermal and economic point of view (Ref 27).

To avoid heating of the tool frame and thus failure during operation, it is required that heated tool elements and the tool frame be thermally separated. This can be done by using thermal insulations, fluid-cooled plates between tool and tool frame, or by cooling the surfaces with air. When using thermal insulations and cooling plates together, a sufficient thermal separation is possible. Therefore, low flow rates of cooling water are sufficient (Fig. 17). The combined use of insulation and air is not recommended, because even if the flow velocity is 50 m/s (2000 in./s) (compressed air), the cooling of the forming machine is insufficient (Ref 27).

The limit drawing ratio reaches a maximum in the temperature range from 200 to 250 °C (390 to 480 °F), which activates further slip planes. Above this temperature level, the work-softening behavior of the material prevails, and the limit drawing ratio decreases (Ref 15, 17).

Deep drawing of components with complex and/or irregular geometries is accompanied by nonuniform conditions of stress and strain in the flange area. While the straight and slightly bent sides of the drawn part mainly undergo radial stretching (less true strain), the corners are dominated by an overlapping of radial stretching and tangential upsetting (high true strain) (Ref 28, 29). From the resulting differences in equivalent strain, it is advantageous to subject the flange area to locally differentiated heating. The corner areas with higher true strains are more heated than the side areas with less true strains. The advantage of this partial heating is the increase of the forming limits by a better load transmission in the material during the deep drawing process, because of the lower work softening in the less heated areas. Furthermore,

Table 7 Results of investigations concerning appropriate heating principles

Criterion	Heating by transfer fluid	Resistance heating		Inductive heating
		Heating cartridge	Tubular radiator	
Transferable amount of heat	Max. allowed oil temperature: 350 °C (660 °F)	Max. allowed oil temperature: 750 °C (1380 °F)		Max. allowed inductor temperature: 70 °C (160 °F) Tool temperature: 250–260 °C (480–500 °F)
Control accuracy	Max. difference of temperature: $\pm 4$ K	Max. difference of temperature: $\pm 0.5$ K		Max. difference of temperature $\pm 0.5$ K
Costs of the heating system	500% (oil preheater, pump, flow control)	100% (temperature-control unit)		1000% (HF-generator, inductor cooler)
Costs of the tool		Similar for all heating principles (construction with milled channels necessary)		
Efficiency	30–58%		94–96%	78–88%

Source: Ref 27

in order to reduce the energy consumption, it is advantageous to heat the side areas of the part less. Figure 18 displays the construction of a partially heated tool. Investigations have proven that a distinct extension of the forming limits is possible by increasing the temperature in the more severely formed areas of the formed part than in the less severely formed zones (Fig. 19).

**Influence of Temperature on Flow Stress.** Figure 20 displays the flow curves of the magnesium alloy MgAl3Zn1 (AZ31) at the temperature range of 250 to 400 °C (480 to 750 °F) and at two strain rates, 1/s and 10/s.

The flow curves decrease at all tested temperatures. The gradient of the curve quantifies the work softening. The decrease of the flow curves is stronger at all temperatures under recrystallization temperature (Ref 30). In these tests, partial microcracks or microporosities appear, which lead to strong work softening or to the crack of the specimen. At temperatures above 300 °C (570 °F), higher strain rates can be obtained without shear fracture of the specimen under 45° to the deformation direction (Fig. 21). Above the recrystallization temperature, the decrease of the flow curves can be explained by an overlapping of work-hardening mechanisms and a recovery of the material. The recovery of the material has a strong influence on the decrease of the flow curve (Ref 31).

**Influence of Strain Rate on Flow Stress.** Figure 22 shows flow curves for MgAl3Zn1 (AZ31) at the temperature of 300 °C (570 °F) and at different strain rates. The yield stresses were determined by means of the uniaxial upsetting test.

The stresses increase at a higher deformation rate and decrease at a higher forming tempera-

ture. Due to the temperature increase of the specimens during forming, the yield stress decreases at higher degrees of deformation. These temperature differences may amount to 70 °C (160 °F). The higher the inner resistance to a deformation within a specimen, the higher the temperature increase (Ref 31).

### Hot Forming Practices

**Sheet and Plate.** Rolled magnesium alloy products include flat sheet and plate, coiled sheet, circles, tooling plate, and tread plate. These products are supplied in a variety of sizes.

The ability to use increased section thickness without weight penalty is of particular importance in designs that employ magnesium sheet. Thick-sheet construction provides the rigidity necessary in a structure, without the need for costly assembly of ribs and similar reinforcing members.

Rolled magnesium alloy products can be worked by most conventional methods. For severe forming, sheet in the annealed (O temper) condition is preferred. However, sheet in the partially annealed (H24 temper) condition can be formed to a considerable extent. Because heat has significant effects on properties of hard-rolled magnesium, properties of the metal after exposure to elevated temperature must be considered in forming. The design curves shown in Fig. 23 give minimum values suitable for design use. Although the curves are based primarily on tests of sheet 1.63 mm (0.064 in.) thick or less, check tests indicate reasonable applicability for thicknesses up to 6.35 mm (0.250 in.).

Figure 23 shows how the properties of AZ31B-H24 change with exposure time at various temperatures. The curves have been extrapolated above the typical property levels of AZ31B-H24 sheet. Thus, if the value selected from a curve exceeds the actual property level of the material before exposure, the actual figure

**Fig. 20** Flow curves of extruded MgAl<sub>3</sub>Zn<sub>1</sub> (AZ31) at different temperatures and strain rates determined in the uniaxial upsetting test

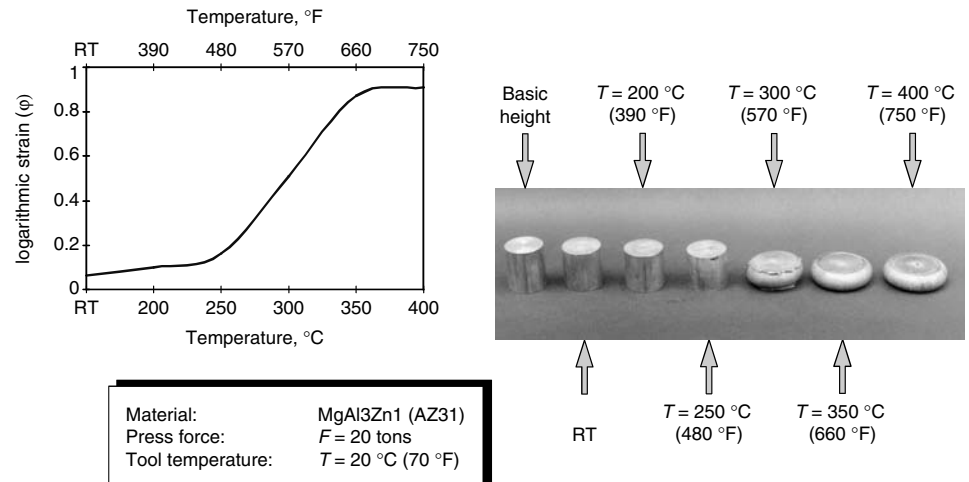

must be used. Also, it should be kept in mind that the effects of multiple exposures at elevated temperature are cumulative.

AZ31B-H24 sheet is commonly hot formed at temperatures below 160 °C (320 °F) to avoid annealing it to room-temperature property levels lower than the specified minimums. Annealing is a function of both time of exposure and temperature; thus, temperatures higher than 160 °C (320 °F) can be tolerated if exposure is carefully controlled.

**Thermal Expansion.** Magnesium alloys have a very high rate of thermal expansion. At 260 °C (500 °F), for example, the thermal expansion of magnesium is more than twice that of steel. Therefore, when parts made of magnesium alloys are hot formed in tool steel or cast iron dies, the difference in the thermal expansion of the tool material and the work metal must be considered.

Figure 24 shows the relation between the size of a magnesium part and the size of a steel die at 20 °C (70 °F) and at 205 °C (400 °F). The dimensional factor need not be applied when the dies are made of zinc or aluminum alloys, because the coefficients of expansion of these alloys are similar to those of magnesium alloys.

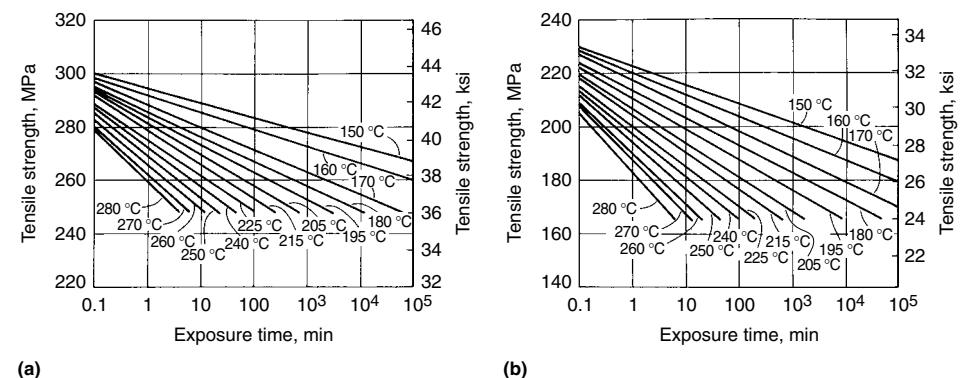

**Precautions.** Magnesium alloy stock to be hot formed must be clean. Protective coatings,

Data are based on tests of sheet 1.63 mm (0.064 in.) thick, and have reasonable applicability for thicknesses up to 6.35 mm (0.250 in.).

oil, dirt, moisture, or other foreign matter must be removed.

Dies, punches, and form blocks should be clean and free of scratches; tooling should be cleaned with solvent. Rust, scratches, and minor imperfections can be removed by light polishing with fine-grit abrasive cloth. However, polishing must not alter the dimensions of the tool.

In forming, the possibility of fire due to ignition of magnesium is remote. However, an ample supply of suitable fire-extinguishing material, such as dry sand or commercially available powder, must be kept in the work area.

**Heating Methods.** Electric heating elements often are used for heating dies and other forming tools. Electric-resistance heating can be used for heating some dies. Low-voltage high-amperage current is passed into the die through conducting grips or clamps.

Radiant heating with electricity and gas is useful for heating dies and workpieces in some applications. Radiant heating is particularly useful for rapid heating of the workpiece and for use in rapid-action presses. Also, with this heating method, cloth covers can be used on the workpiece to minimize heat loss.

Infrared heating is also commonly used. A bank of infrared lamps is the most common method, but gas-fired units are also used. The principal advantage of infrared heating is that only the die and workpiece are heated and not the surrounding area. Also, the cost of heating is less, and working conditions are cooler and less hazardous.

Gas heating often is advantageous, because the installation of equipment is simple and fuel cost is generally low. Burners up to 1.9 m

(75 in.) long can be formed and welded from 19 mm ( $\frac{3}{4}$  in.) black iron pipe; 25 mm (1 in.) pipe is suggested for burners more than 1.9 m (75 in.) long. Burners are attached to the dies so that the flames touch the die surface. Hollow punches can be heated by a burner inside the punch.

Four gas-mixing systems are used for heating tools and dies:

- Simple venturis, in which gas flows through a mixer that draws in air
- Proportional mixers, which use compressed air flowing through a venturi (or an air injector) that pulls the gas into the burner at atmospheric pressure
- A gas-air carburetor system, which uses a low-pressure turbocompressor to compress the gas-air mixture. The carburetor holds a constant fuel-to-air ratio regardless of the volume of flow.
- A venturi mixing system combined with turbocompressors, which gives accurate temperature control with minimum overshoot

Heat-transfer fluids are used for heating platens, form blocks, drop hammer dies, and other forming tools large enough to have passages in the die. Heating by this method is rapid and permits good temperature control. Heat-transfer fluids with a working-temperature range of 150 to 400 °C (300 to 750 °F) are available. Hot oils, natural and synthetic, that can withstand temperatures up to 345 °C (650 °F) are commonly circulated in passages in the dies. Steam is readily available and is circulated through ducts in the tools or dies, but its maximum temperature is usually approximately 175 °C (350 °F). Commercially available equipment for use with heat-transfer fluids includes vapor generators, circulating mechanisms, and means for temperature control.

**Temperature control** is important. For forming a few pieces, contact pyrometers or temperature-sensitive crayons are satisfactory for determining temperature. Blue carpenter's chalk can sometimes be used. A streak of this chalk on a metal surface will turn white at approximately 315 °C (600 °F).

Automatic temperature controls are essential for most magnesium-forming operations. Radiant and infrared heat are more difficult to control than other kinds of heat. One type of infrared lamp has a control that extends or retracts the lamp when the tool or workpiece has reached the desired temperature. Another temperature control for infrared heating consists of a special radiometer that senses only the heat radiated by the surfaces being heated.

To maintain the desired temperature, controls used in gas-heating systems usually operate by adjusting a solenoid valve in the line to lower or raise the flame. Electric heating by elements, resistance heating, and heating by means of heat-transfer fluids usually provide good temperature control.

## Lubricants (Ref 33)

Generally, lubrication is more important in hot than in cold forming of magnesium alloys, because the likelihood of galling increases with the increase of temperature.

Lubricants used in forming magnesium alloys include mineral oil, grease, tallow, soap, wax, molybdenum disulfide, colloidal graphite in a volatile vehicle, colloidal graphite in tallow, and thin sheets of paper or fiberglass.

**Selection of a lubricant** depends primarily on forming temperature. For temperatures up to 120 °C (250 °F), oil, grease, tallow, soap, and wax are generally used.

In spinning, it is essential that the lubricant cling to the work metal; otherwise the lubricant will be thrown off by centrifugal force. This is not a problem when drawing in a die or bending in a press brake.

Frequently, a lubricant that is used for other operations in the plant can be used, up to a forming temperature of 120 °C (250 °F). It is common practice to use the lubricant that can be most easily removed after forming and to apply it by roller coating or swabbing. Sometimes, the lubricant is applied to both the work metal and the tools.

When forming is done at temperatures above 120 °C (250 °F), the selection of a lubricant is more limited; ordinary oil, grease, and wax are eliminated. Although colloidal graphite can be applied at any temperature that is used for forming magnesium alloys, its use is usually avoided, because graphite is difficult to remove and interferes with subsequent surface treatments.

A soap lubricant is acceptable for temperatures as high as 230 °C (450 °F). This compound is an aqueous solution and is applied to the work metal by dipping, brushing, or roller coating. After coating, the work metal blanks are dried in still or forced air. After drying, the blanks can be stored for an indefinite period for future processing because the dried lubricant is stable. Lubricant that remains after forming can be completely removed by cleaning in hot water.

When forming temperatures are higher than 230 °C (450 °F), the choice of lubricant is restricted to colloidal graphite or molybdenum disulfide. Graphite in a vehicle such as spirits (2% graphite) is widely used; for spinning, the graphite is mixed with tallow to improve adherence.

**Procedures.** Lubricants should be cleaned from parts as soon as possible after forming, to prevent corrosion and to avoid difficulty in their removal. Colloidal graphite is particularly difficult to remove if allowed to remain on parts for any length of time.

Because some work lubricants cannot be tolerated at any forming temperature, thin sheets of paper or fiberglass (depending on temperature) are placed between the work metal and the tools. More information on lubricants for sheet forming is available in the article "Selection

**Fig. 24** Dimensional relations of a magnesium alloy workpiece and a steel die at room temperature and at a forming temperature of 205 °C (400 °F). Room-temperature dimensions of the steel die are determined by multiplying the design dimensions of the magnesium part by 1.00270. Dimensions given in inches

and Use of Lubricants in Forming of Sheet Metal" in this Volume.

## Press-Brake Forming

The press-brake forming of magnesium alloys is the same as it is for other metals, except that the work metal and the dies are usually heated. Top and bottom dies can be made of steel, or if the workpiece permits cold forming, the steel punch can be bottomed in a rubber die held in a retaining box. Metal punches and dies should be highly polished to prevent marking of workpiece surfaces.

A preferred method of heating the punch and die for hot forming is shown in Fig. 25. When only a few workpieces are to be formed, heating with a gas torch is satisfactory; however, care must be taken to ensure that the area of the workpiece to be formed is uniformly heated. If the press-brake die is not heated, the workpiece should be heated to the maximum allowable temperature and formed quickly, before the tools can cool the work metal too much.

## Deep Drawing (Ref 14)

Hydraulic presses are usually preferred for deep drawing magnesium alloys because they can operate at slower and more uniform speeds. Mechanical presses are used, however, for making draws that are not too severe. The force required for deep drawing magnesium to a cylinder can be estimated by the following empirical formula:

$$L = \pi d t S (D/d - k)$$

where  $L$  is the press load in Newtons,  $d$  is the cup diameter in mm,  $D$  is the blank diameter in mm,  $t$  is the blank thickness in mm,  $S$  is the tensile strength at temperature in MPa, and  $k$  is a constant, which is between 0.8 and 1.1 for magnesium conversion factor: Newtons  $\times 0.225 = \text{lbf}$ .

**Fig. 25** Preferred method of heating a punch and die for hot forming magnesium alloys on a press brake

The values for the tensile strength of a particular magnesium alloy at elevated temperatures can be used to estimate the force that will be needed to make any given draw. The holddown force needed to prevent wrinkling depends on blank thickness and temperature but is between 1 and 10% of the drawing force.

**Blankholder pressures** for magnesium alloys vary from the lowest obtainable to as much as 5 MPa (700 psi). In average draws, the blankholder pressure is usually 345 to 1380 kPa (50 to 200 psi). To secure proper wall thinning, blankholder pressures are obtained by trial and error.

**Die Heating.** Electric heating elements are usually used for heating the tools, although when intricate parts are drawn, gas-ring burners provide more flexibility, particularly if the work metal is likely to pucker. The base of the punch sometimes can be heated.

Another type of differential heating is used in the production of workpieces that have a slight crown. When the crown must be held to close tolerance, burners with separate controls are provided inside and outside the die. For more crown, the outside of the mating die is heated to a higher temperature than the inside. When the workpiece reaches die temperature and the outside of the sheet is hotter than the inside, the work metal retracts upon removal of the die, thus causing the crown to form. Alternatively, to eliminate crowning and obtain flatness, the inside of the die is heated to a higher temperature than the outside.

**Drawability.** Annealed magnesium alloy sheet can be cold drawn to a maximum reduction (blank diameter to cup diameter) of 15 to 25%. With heat, drawability is greatly improved, and up to 70% reduction is possible. The drawability, or percentage of reduction in blank diameter, is calculated by the formula:

$$\text{Percentage reduction} = \frac{D - d}{D} \times 100$$

where  $D$  is the blank diameter before drawing, and  $d$  is the diameter of the punch.

While multiple draws can be made at room temperature to arrive at a final deep draw, in practice all deep drawing of magnesium is done at elevated temperatures. The effect of temperature on lubrication practice and the modifications of tool design required to account for thermal expansion must therefore be considered. At high temperatures, magnesium alloys can

be deep drawn in one operation to a cylinder by a reduction of as much as 75%.

In general, as the temperature is raised and the speed of the draw is reduced, the greater will be the amount draw possible (Table 8). The speed of drawing can vary from approximately 4 to as much as 2500 cm/min (1.5 in./min to 82 ft/min); the speed selected will depend on the severity of the draw and any compromise required between using single and multiple draws, the latter requiring additional tooling.

Drawability is also influenced by the shape of the workpiece. A maximum drawability of 70% is for drawing a cylindrical cup. Square and rectangular boxes, for example, seldom are drawn as severely.

In addition, the die radius of curvature, which is a measure of the severity of the bend required as the blank is pushed through the die, is another consideration of severity of a draw, along with the radius of curvature between two side walls for boxlike shells, and the radius of curvature of the punch, which forms the radius between the side wall and the bottom. All of these parameters must be kept within workable limits if the draw, or series of draws, is to be successful.

As a round blank is drawn into a cup, the metal that will be forced through the die must first be compressed from its radius to the radius of the die opening. Because the volume occupied by the metal does not change, the blank becomes thicker as it reaches the die and remains thicker as it bends to go through the die. After being bent over the radius and stretched into the wall of the cup, thinning occurs. Therefore, die design must provide sufficient clearance to allow for the thickening that occurs as the blank is drawn to the die. A guide for the required clearances is:

Blank thickness		
mm	in.	Clearance
0.40	<0.016	1.07–1.09 $t$
0.40–1.3	0.016–0.050	1.08–1.10 $t$
1.3–3.2	0.050–0.125	1.10–1.12 $t$
>3.2	>0.125	1.12–1.14 $t$

$t$ , blank thickness

Because, during the draw, the metal that has reached the wall is thinner than the metal that has just passed the die radius, the metal in the wall must support a higher stress than the metal at the radius in order to continue stretching the entire blank into the wall. This is possible when the draw is done at room or low temperatures

**Table 8** Drawability of AZ31B-O at various temperatures and speeds

Drawing temperature		% reduction		
°C	°F	At 600 cm/min (235 in./min)	At 1500 cm/min (590 in./min)	At 2400 cm/min (945 in./min)
20	70	14.3	14.3	...
120	250	30.3	30.3	...
200	390	58.6	57.1	53.8
260	500	62.5	61.3	53.8

76 mm (3 in.) diam cylindrical cup; sheet thickness, 1.65 mm (0.064 in.); draw-ring radius, 6 $r$ ; punch radius, 10 $r$

because the metal that has been stretched has been strengthened by work hardening. There is added flexibility, however, when the draw is at elevated temperatures; the punch can be kept at a lower temperature than the die, resulting in higher strength in the cooler wall metal than in the warmer metal at the die.

**Effect of Speed on Drawability.** Drawability at any temperature varies with the speed of drawing, which ranges from 0.6 to 405 mm/s (1½ to 960 in./min). Large reductions (70%, for example) require slower speeds than do moderate reductions (up to 55%).

Reductions up to approximately 55% can often be made on high-speed hydraulic or mechanical presses. Also, milder draws permit lower forming temperatures, and costs can be reduced because strip feeding, blanking, lubrication, trimming, and cleaning can be simplified.

For most parts, however, depth of draw is not a primary consideration, and usually no trouble is experienced in drawing to the depth required. More trouble is encountered in keeping the metal free from puckers in parts with rounded corners or contours. Temperatures above those required for maximum drawability are often necessary to eliminate these puckers. On unusual or difficult jobs, it may be necessary to vary the procedure to obtain minimum scrap.

**Redrawing.** The possibilities inherent in two-step draws are illustrated by the following parts: In the first operation, 610 mm (24 in.) blanks of 0.64 mm (0.025 in.) annealed sheet were drawn to a cup 200 mm (8 in.) in diameter by 400 mm (16 in.) in depth; they were redrawn to a cup 140 mm (5½ in.) in diameter by 585 mm (23 in.) in depth. Starting with a rectangular blank of 1.3 mm (0.051 in.) AZ31B-O, 455 by 485 mm (18 by 19 in.), a rectangular box 111 by 273 by 165 mm (4⅜ by 10¾ by 6½ in.) in depth was drawn in the first operation. This box was then redrawn into a rectangular box 89 by 254 by 171 mm (3½ by 10 by 6¾ in.) in depth having 5.6 mm (7/32 in.) corner radii.

**Choice of die materials** is chiefly influenced by the severity of the operation and the number of parts to be produced. For most applications, unhardened low-carbon steel boiler plate or cast iron is satisfactory. For runs of 10,000 parts or more, for maximum surface smoothness, or for close tolerances where no significant die wear can be allowed, hardened tool steels are recommended. Tool steels W1 or O1 are satisfactory for extremely long runs (1 million parts). For the most severe draws, however, the more abrasion-resistant tool steels, such as A2 or D2, will probably be more satisfactory and economical. For room-temperature drawing, it is usually desirable for die steels to be heat treated to obtain near-maximum hardness in service. However, for elevated-temperature drawing, the maximum temperature to which the dies will be exposed in drawing must also be considered. In this situation, the dies must be tempered slightly above the maximum service

temperature, even though some hardness may be sacrificed.

## Manual Spinning

Various conical and hemispherical shapes can be produced from magnesium alloys by manual spinning. Because tooling is inexpensive, manual spinning of small quantities is often more economical than press forming. When press tooling would be complex, manual spinning may be used for medium to large production quantities.

**Equipment and tooling** for manual spinning of magnesium alloys are essentially the same as those used for other metals (see the article "Spinning" in this Volume), except that when magnesium alloys are to be heated, the mandrels (spin blocks) should be made of metal, with provision for controlled heating of the work metal.

For spinning a few pieces, it is common practice to heat the blanks with a hand torch, using temperature-sensitive crayons to indicate the temperature. For production spinning, however, the use of a thermostatically controlled burner on the lathe is preferred.

**Procedure.** Annealed sheet is usually used in spinning. Manual spinning depends to a large extent on operator skill, especially when spinning magnesium alloys, which are more temperature sensitive than most metals.

Many shapes can be spun from unheated blanks by a skilled operator, especially when thin sheet is used, because friction between the spinning tool and workpiece generates a substantial amount of heat. As severity of sheet thickness increases, the work metal must be heated. Temperatures of 260 to 315 °C (500 to 600 °F) are common.

Whether spinning is done hot or cold, a lubricant should be used (see the section "Lubricants" in this article). Spindle speed should be such that the speed of the edge of the blank is approximately 610 m/min, or 2000 surface feet per minute (sfm), when spinning begins.

**Tolerances.** Typical tolerances that can be maintained in manual spinning of magnesium alloys are as follows:

Workpiece diameter		Tolerance	
mm	in.	mm	in.
<455	<18	±0.8	± 1/32
455–915	18–36	±1.6	± 1/16
>915	>36	±3.2	± 1/8

**Spinning Extrusions.** Manual spinning can be used either to close or flare the ends of extruded round tubing.

Closing the ends of tubes is done by slowly forcing a rotating hemispherical cup over the end of the tube until the end is closed and has assumed the hemispherical shape of the cup (spinning tool). This can be done on almost any machine that can hold the workpiece and rotate the cuplike tool. A drill press is frequently used. The use of grease or soap as a lubricant is help-

ful in producing a better workpiece finish and prolonging the life of spinning tools. In most applications, tube ends can be closed without the use of heat.

Tube flaring is done either by inserting a stationary mandrel into the tube and pushing it out against a stationary die on the outside, or by spinning or rolling the flare against a stationary outside die with a conical, rotating, inside mandrel. The shape required for the flare usually determines the preferred procedure.

Tube-flaring machines have a stationary outside die and conical, rotating, inside spindle with adjustable eccentricity, the axis of which rotates off center at approximately 1600 rpm. The eccentric spindle forces the tube against the outer die to form the flare. In the flaring of magnesium alloy tubes, the outer die should be heated, preferably by electric heating elements in the die holder, to a preferred temperature of approximately 260 °C (500 °F). The tube to be flared is preheated to the same temperature. Lubrication may be required during tube flaring. The lubricants recommended for spinning can be used.

## Power Spinning

Power spinning (shear spinning) can be used for magnesium alloys. Both cone spinning (spinning in accordance with the sine law) and tube spinning (spinning in which metal displacement is strictly volumetric) are used for magnesium alloys.

**Equipment and Tooling.** Special machines are used in the cone and tube spinning of magnesium alloys. However, the equipment used in power spinning is the same as that used for other metals (see the article "spinning" in this Volume), except when hot spinning is done; then, torches or other heating equipment must be added to the machine. Consequently, the mandrels and rollers must be made from an alloy tool steel that will not be softened by heat. Tool steels such as H12 or H13 hardened to 54 to 58 HRC are used in many applications.

**Procedure.** Magnesium alloys are sometimes power spun without heat, but more often the major portion of the reduction is performed hot and finished cold, or is rough worked hot and then finished at a somewhat lower temperature (warm). For the most successful results, a definite procedure of alternate spinning and heating should be followed, whether the metal is finished cold or warm. Table 9 gives recommended procedures for the two methods often used for alloys HK31A and HM21A. The use of the procedures outlined in Table 9 has resulted in total wall thickness reductions as high as 80%.

## Rubber-Pad Forming

Hydraulic presses are generally used for the rubber-pad forming of magnesium alloys.

Tooling is simple because only a form block is used (Fig. 26). A conventional die is not needed.

For forming at room temperature, particularly for limited use, form blocks can be made of wood or masonite; or for higher production runs, they can be made of aluminum, zinc, or magnesium, which are more durable than wood or masonite. However, large radii must be used in cold forming.

When rubber-pad forming at elevated temperature, form blocks must be made from metal that will not creep excessively at the working temperature and pressure; magnesium, aluminum, or zinc can be used up to approximately 230 °C (450 °F). However, forming at temperatures higher than 230 °C (450 °F) requires steel form blocks.

Specially compounded grades of solid rubber or laminated sheets are used for the rubber pad when forming at temperatures up to 315 °C (600 °F). Hardness of the rubber is important; Durometer A 40 to 70 is the common range.

**Heating.** As shown in Fig. 26, the heating elements heat the steel platen, and the heat is transferred to the form block, which is not fastened to the platen, by conduction. Alternatively, the form block can be heated separately in an oven and then placed on the platen. With this method, a fireproof blanket often is placed between the heated form block and the cold platen for insulation. Usually, blanks are heated in ovens situated near the press to minimize loss of heat.

**Forming Pressure.** Pressure for rubber-pad forming is a function of sheet thickness and forming temperatures; 6200 kPa (900 psi) is adequate for most work.

Rubber-pad forming is generally done by shaping the blank around a form block with pressure from the rubber pad. However, when pressure must be concentrated at one point, or metal flow must start before general pressure is applied, deflector bars are used (see the article "Rubber-Pad Forming and Hydroforming" in this Volume).

Some severe forming is done in two operations: The workpiece is partly formed, is removed from the press for hand smoothing of wrinkles, and then is returned to the press for final forming under full pressure. In one-operation forming, thin throw sheets of heat-resistant rubber can be placed over the blank, or attached to the pad, to protect the rubber.

**Shrink flanges** that are wrinkle-free can be made with a higher percentage of compression from magnesium alloys than from other metals, such as aluminum, of the same gage. Minor wrinkles can be hand corrected after flanging. If the part is likely to wrinkle severely, scalloped cutouts or recesses in the form blocks may correct this condition. A draw plate to iron out wrinkles during forming is often helpful.

**Stretch flanges** of up to 40% stretch in hard-rolled magnesium alloy sheet (H24 temper) and 70% in annealed sheet (O temper) can be made by rubber-pad forming. The ranges of stretch flange limits for various thicknesses of AZ31B-O and AZ31B-H24 alloy sheet rubber pad formed at 150 °C (300 °F) are shown in Fig. 27.

A minimum flange radius of  $5t$  is suggested for alloy AZ31B-H24 at 160 °C (320 °F). The radius of the die should be approximately  $1/2t$  less to compensate for springback.

**Beads.** In rubber-pad forming, both internal and external beads can be formed in magnesium alloy sheet. Usually, external beads are easier to produce, although wrinkling is slight in both types.

Severity of forming internal and external beads is expressed as the ratio  $w/h$ , where  $w$  is the width of the bead, and  $h$  is the height of the bead. Beading is essentially a stretching operation, and this  $w/h$  ratio is related to the maximum percentage of stretch obtained in a given bead.

External beads can be made to equal or more severe ratios; the minimum bead margin should be 9.6 mm (0.38 in.), and beads should be separated by a minimum centerpoint distance of 19.3 mm (0.76 in.).

**Hand forming** can slightly improve the definition of a part after rubber-pad forming, while the form block and workpiece are still hot. A leather or plastic forming tool can be used to correct minor irregularities or improve flange angles. To avoid damage to the form block, hard tools should not be used.

## Stretch Forming

The stretch forming of magnesium alloys is the same as it is for other metals, except that magnesium alloys are generally stretch formed at elevated temperatures. The fundamentals of stretch forming, compression forming, and radial draw forming are described in the article "Stretch Forming" in this Volume.

Dies, or form blocks, made from magnesium, aluminum, or zinc alloys are suitable for forming at temperatures up to 230 °C (450 °F). Concrete form blocks containing wire mesh heated by electrical resistance may also be used

**Table 9** Procedures for power spinning two magnesium alloys to obtain acceptable properties

Alloy	Procedure
<b>Cold finishing</b>	
HK31A	Hot work roughly to shape at $425 \pm 30$ °C ( $800 \pm 54$ °F). Heat treat for 30–60 min at $455\text{--}480$ °C ( $850\text{--}900$ °F)(a). Cold work to a total reduction in thickness of at least 25% using low reductions per pass. Heat 1 h at $315\text{--}330$ °C ( $600\text{--}625$ °F)
HM21A	Hot work roughly to shape at $455 \pm 10$ °C ( $850 \pm 18$ °F). Heat treat for 30–60 min at $480\text{--}510$ °C ( $900\text{--}950$ °F)(b). Cold work to a total reduction in thickness of 15–25% using low reductions per pass. Heat 1 h at $370 \pm 16$ °C ( $700 \pm 29$ °F)
<b>Warm finishing</b>	
HK31A	Hot work roughly to shape at $425 \pm 30$ °C ( $800 \pm 54$ °F) if necessary. Heat treat for 30–60 min at $455\text{--}480$ °C ( $850\text{--}900$ °F)(a). Warm work at $315\text{--}370$ °C ( $600\text{--}700$ °F) to a total reduction in thickness $>50\%$ with a minimum number of passes. Heat 16 h at 205 °C (400 °F)
HM21A	Hot work roughly to shape at $455 \pm 30$ °C ( $850 \pm 54$ °F) if necessary. Heat treat for 30–60 min at $480\text{--}510$ °C ( $900\text{--}950$ °F)(b). Warm work at $315\text{--}370$ °C ( $600\text{--}700$ °F) to a total reduction in thickness $>50\%$ with a minimum number of passes. Heat 16 h at 230 °C (450 °F)

Note: Properties obtained will approach those of the H24 temper for HK31A and the T8 temper for HM21A. (a) Fairly rapid cooling is desirable but less critical than for HM21A. (b) Should be cooled from the heat treating temperature to 315 °C (600 °F) or below within 5 min

at temperatures up to 230 °C (450 °F). For temperatures higher than 230 °C (450 °F), cast iron form blocks are used.

To prevent tearing of the work metals, grippers used in the forming of magnesium alloys should not have serrated jaws. Coarse emery paper or cloth can be placed between the work metal and the jaws to preclude tearing.

Tools and work metal can be heated by electric heating elements or by radiant heat. Proper distribution of heat is important, and units should be placed at critical forming areas.

For differential stretching of sheet over forms of low curvature, the practical maximum stretch is approximately 15%. The maximum is 12% if allowance (overstretch) is made for springback; however, normally little springback is encountered at elevated temperatures; therefore, an addition of 1% to the total stretch usually compensates for any springback that may occur.

Although freedom from wrinkles is an advantage of stretch forming in most applications, wrinkles can be a problem when making asymmetrical low-curvature parts. Wrinkles can be controlled by including proper restraints in the die. The skill of the operator largely determines where such restraints are needed.

## Drop Hammer Forming

Drop hammer forming is used for producing shallow depths and asymmetrical shapes in magnesium alloys when quantities are small and for applications requiring minimum springback. Successful results depend on operator skill. Except for heating, drop hammer forming of magnesium alloys is the same as it is for other metals (see the article "Drop Hammer Forming" in this Volume).

Zinc alloy can be used for both punch and die. Lead punches are sometimes used, but lead pickup can cause corrosion of the sheet. For production quantities greater than approximately 50 pieces, however, cast iron punches and dies are recommended, because zinc alloy tools lose their shape at these quantities.

Annealed sheet is preferred for drop hammer forming. Blanks should be heated near the hammer, because the work cools rapidly—usually 16 to 25 °C (30 to 45 °F) in 5 s. Ten blows may be needed to form a part, with reheating between blows—5 min for metal thicknesses up to 1.3 mm (0.051 in.) and 9 min for thicknesses of 1.3 to 3.18 mm (0.051 to 0.125 in.).

Heat-resistant rubber pads are often used in the dies for preliminary forming and are removed before final forming.

Dies can be heated in an oven near the hammer, or by torches or ring burners during operation. Small dies can be used on an electrically heated cast iron platen on the hammer bed, but this method is not practical for large dies. Heating of the punch and die by electric heating elements or by a heat-transfer fluid is also used.

The elevated temperatures used in drop hammer forming of magnesium alloys can reduce or eliminate springback; therefore, the maximum practical temperature should always be used. The rate of deformation must be carefully controlled, especially when deformation of the work metal is severe, or when the metal is in the H24 temper. For workpieces that require severe forming, the punch is lowered slowly, and forming is completed with subsequent blows. Tolerances of  $\pm 0.76$  mm ( $\pm 0.030$  in.) can be maintained in production.

## Precision Forging

Precision forging for the near-net shape production of high-quality components is a relatively new method of die forging (see the article "Precision Hot Forging" in *Metalworking: Bulk Forming*, Volume 14A of *ASM Handbook*, 2005). With steel and aluminum, the procedure has been successfully used in the automotive and airplane industry. Besides simple precision-forged workpieces, no new developments for magnesium have been made in recent years.

Precision forging, which was developed as a special method of die forging, is realized in a closed die without room for compensation, so that a flash is almost nonexistent. Workpieces can be produced with tolerances, where machining can be reduced to a minimum. Forging processes of magnesium alloys, as near-net shape forming technologies, have the potential to become more and more relevant in the production of lightweight applications. In particular, aerospace and automotive components, with their high requirements in view of safety and weight, provide a range of applications for forging processes. Not only aluminum or steel parts but even plastic or fiberglass components could be replaced by magnesium alloys (Ref 34). Precision forging has the following advantages compared to conventional die forging methods:

- Production of near-net shape workpieces
- More economic use of material because of flashless forging
- Reduction of machining processes

**Precision Forging and Forging Simulation of Test Specimens.** To investigate the temperature dependence of the forgeability of magnesium alloys, the spike forging test can be used. The shape of the test specimens was defined in a way in which the relevant material flow processes could be investigated. The height of the cone and the broadening of the flange could be used to assess the formability of the material under the particular forging condition. The tool temperatures (upper and lower die) and the heating temperature are varied in relevant ranges.

Based on the material data of the fundamental investigations, the forging process is simulated.

The simulated material flow is in good accordance with the experiment (Fig. 28). Forging processes for the considered alloy can be simulated by verifying the material description on which the simulation is based and which was obtained by experimental material data.

During the forging operation, the microstructure recrystallizes. Due to the finer grain, the hardness (Brinell) of the forged specimen is higher than the hardness of the initial material. It decreases with increasing tool temperature and seems to be more sensitive to tool temperatures than the initial workpiece temperature. Although the highest values can be achieved at low initial temperatures, under these conditions, high punch forces, which are normally limited by the press, are necessary for complete form filling (Ref 32).

**Precision Forging of a Sprocket.** Based on information from the test specimens, a tool system for the precision-forging process of a sprocket was developed (Fig. 29) (Ref 32).

The sprocket was forged in one hit from a cylindrical billet on a screw press with a high punch speed of 365 mm/s (14 in./s). The investigations show that complete die filling for components with slim variant structures can be realized by thermally controlled tools. An optimized die filling was reached at billet temperatures between 300 and 380 °C (570 and 715 °F),

Fig. 28 Test specimens by experience and simulation. Source: Ref 32

Fig. 29 Forged sprocket of MgAl<sub>3</sub>Zn<sub>1</sub> (Az31). Source: Ref 32

**Fig. 30** Finite element method (FEM) simulation of material flow and form filling. Source: Ref 32

with a die temperature of 250 °C (480 °F) for the upper die and 300 °C (570 °F) for the lower die. Some graphite and graphite-free lubricants were tested, and the best results were achieved for Molykote (Dow Corning Corp.), a graphite-based MoS<sub>2</sub> oil. Numerical thermomechanical-coupled finite element simulation, based on the elaborated material properties for the considered magnesium alloys, enables the layout of forging processes. The temperature distribution, die filling, punch forces, as well as the tool loading can be predicted. The die filling starts with the compression of the initial cylindrical geometry, followed by a radial material flow. The shape of the teeth is realized at the end of the forging operation (Fig. 30).

# Forming of Nickel and Cobalt Sheet Alloys\*

Revised by Howard W. Sizek, Air Force Research Laboratory

NICKEL AND COBALT ALLOYS are used in a wide range of products and processes where they must resist corrosion and elevated temperatures. These alloys have a wide range of compositions and are often alloyed for specific applications. Table 1 lists the nominal compositions for the nickel and cobalt alloys discussed in this article. Included in this list are some iron alloys with significant levels of nickel,

chromium, and/or cobalt. These alloys are often grouped with nickel and cobalt alloys because of their capabilities in engineering applications. These iron alloys also have forming characteristics similar to the nickel and cobalt alloys.

Depending on the specific alloy, one or more of the following strengthening mechanisms is used in the nickel and cobalt alloys: solid-

solution strengthening, precipitation hardening, and dispersion strengthening. These strengthening mechanisms result from wide-ranging microstructural, compositional, and processing variations. Each of these variations contributes to the response of the material during forming into the final product.

Cold forming is preferred for nickel and cobalt alloys, especially in thin sheets, because most of

these alloys can be hot formed effectively only in a narrow temperature range between approximately 925 and 1260 °C (1700 and 2300 °F). Annealing between cold forming operations is usually preferred to hot forming.

This article discusses forming techniques for these alloys as well as provides several examples of the forming techniques.

## Alloying and Strain Hardening

Strain hardening can be related to the solid-solution strengthening afforded by alloying elements (Ref 3–5). In general, the strain-hardening rates increase with the complexity of the alloy. Accordingly, strain-hardening rates range from moderately low for nickel and nickel-copper alloys to moderately high for the nickel-chromium, nickel-chromium-cobalt, and nickel-iron-chromium alloys. Figures 1 and 2 compare the strain-hardening rates of a number of alloys in terms of the increase in hardness with increasing cold reduction. Note that the strain-hardening rates of the nickel and cobalt alloys are greater than that of 1020 steel, but some are less than that of AISI type 304 stainless steel. Based on this comparison, most nickel and cobalt alloys can be formed by techniques similar to those employed for the forming of AISI 300-series stainless steels. Table 2 lists the Vickers hardness versus percent cold work for a number of nickel and cobalt alloys.

The differences in work hardening and strength between solid-solution-strengthened alloys can be attributed to compositional differences (Table 1). Alloys with the greatest amount of cobalt, such as alloy 25 (UNS R30605) and alloy 188 (UNS R30188), nominally 51 and 39 wt% Co, respectively, require a greater

magnitude of force to form than iron or nickel alloys. These two alloys have the highest hardening rates of the alloys discussed.

Alloys containing substantial amounts of molybdenum or tungsten for strengthening, such as alloy 230 (UNS N06230) or alloy 41 (UNS N07041), are harder to form than alloys with lesser amounts of these elements. These alloying elements not only increase the strength of the alloy but also increase the strain-hardening rate (Ref 5).

Similarly, the age-hardenable alloys have higher strain-hardening rates than their solid-solution equivalents. Aluminum and titanium are added to nickel alloys to provide strengthening by the precipitation of the  $\gamma'$  phase. The volume fraction  $\gamma'$  is a function of the amount of aluminum and titanium present as well as the overall composition. Examples of  $\gamma'$ -containing alloys include alloy 80A (UNS N07080), Waspaloy alloy (UNS N07011), and alloy 214 (UNS N07214), typically containing 15, 20, and 33%  $\gamma'$ , respectively. Although parts from precipitation-hardened alloys are used primarily in the aged state, aluminum and titanium in these alloys increase the strength in the annealed state, increasing the difficulty of forming parts. The hardening curves for alloys 600 and X-750, its precipitation-hardened counterpart, illustrate the contribution of aluminum and titanium to work hardening (Fig. 1). Alloys 690 and 693, an alloy 690 variant with additional aluminum and niobium, illustrate similar hardening effects in data presented in Table 2. As a result of the high strain-hardening rate, many precipitation-hardened alloys require complex production steps to produce satisfactory components.

Because the modulus of elasticity of the nickel alloys is relatively high (similar to that of steel), a

small amount of springback in cold forming operations may be expected. However, springback is also a function of proportional limit, which can increase greatly during cold working of strain-hardenable materials. For instance, a yield strength of 170 MPa (25 ksi) of an alloy in the annealed condition may increase to 520 MPa (75 ksi) during a drawing operation. Therefore, the amount of springback for this alloy must be computed from the 520 MPa (75 ksi) flow stress, rather than from the initial value of the yield strength. A number of nickel and cobalt alloy stress-strain curves through fracture can be found in Ref 6.

## Forming Practice for Age-Hardenable Alloys

To soften the age-hardenable nickel alloys for forming, two types of annealing treatments are used based on the ductility needed for forming and, if subsequent welding is required, the avoidance of adverse metallurgical effects during and after welding. A high-temperature anneal is used to obtain maximum ductility when the formed part will not be welded. A lower-temperature anneal is used when welding is required, but at the expense of forming ductility.

For example, solution annealing of alloy 41 at 1175 °C (2150 °F) followed by quenching in water gives maximum ductility. However, parts formed from solution-annealed and quenched sheet should not be welded; during welding or subsequent heat treatment, they are likely to crack at the brittle carbide network developed in the grain boundaries. A lower annealing temperature, preferably 1065 to 1080 °C (1950 to 1975 °F), results in less sensitization during welding and decreases the likelihood of grain-boundary cracking. Formability is reduced by 10 to 20% but is adequate for most forming operations.

**Cold-Formed Parts for High-Temperature Service.** A part that is highly stressed during cold forming may require heat treatment to avoid excessive creep in service above its recrystallization temperature. Recrystallization of a specific alloy is determined largely by the extent of cold work. In general, increasing the amount of cold work reduces the recrystallization temperature. The grain size and exact composition of the material also complicate prediction of the recrystallization temperature. Alloys used for high-temperature service are frequently used in the grain-coarsened condition at service temperatures above 595 °C (1100 °F).

Generally, cold-formed nickel alloys should be heat treated if they have been strained in either tension or compression by more than 10% and will be in service at temperatures above 650 °C (1200 °F). Sheet producers should be consulted for the proper thermal treatments.

In certain alloys, heavy cold working (for example, highly restrained bending) followed by exposure at moderate to high temperatures (for example, stress relieving or age hardening) can

**Fig. 1** Effect of cold reduction on the hardness of various nickel alloy sheet materials and, for comparison, aluminum, copper, type 304 stainless steel, and low-carbon ferritic steel

lead to cracking. In age-hardenable alloys, the combination of high residual tensile stress and the stress associated with the aging response may exceed the stress-rupture strength of the material. In non-age-hardenable alloys, excessive cold

working of coarse-grain material (grain size of ASTM No. 5 or coarser) without the recommended intermediate annealing can cause cracking during subsequent exposure at stress-relieving or annealing temperatures. Testing the

material under actual conditions of forming and heating will determine its susceptibility to cracking. Springs can be cold formed from age-hardenable alloys in the annealed or cold-drawn temper. For service at temperatures above 315 °C (600 °F), springs should be solution annealed before aging to prevent loss of strength from relaxation.

Temper

Most cold forming operations require the use of annealed material. However, the softer alloys, such as nickel 200, the NILO alloys, and alloy 400, are frequently used in 1/8-hard and 1/4-hard tempers for improved shearing and piercing. To obtain the fine grain structure that is best for cold forming, the nickel and cobalt alloys must be cold worked (reduced) beyond a critical percentage reduction and then annealed. The critical amount of cold work varies with the alloy and with the annealing temperature but is usually 8 to 10%. Reheating metal that is only slightly cold worked can result in critical grain growth, which can cause orange-peel or alligator-hide effects in subsequent forming operations.

For example, an alloy X (UNS N06002) workpiece, partly formed, stress relieved, and then given the final form, had severe orange peel on much of its surface. The partial forming resulted in approximately 5% cold working, and during stress relief, an abnormally coarse grain structure developed. The problem was resolved by making certain that the metal was stretched 10% or more before it was stress relieved. In addition, stress relieving was done at the lowest temperature and shortest time that could be used, because higher temperatures and longer times increased grain growth. Optimal time and temperature were determined by hardness testing.

Severely cold-formed parts should be fully annealed after final forming. If annealing causes distortion, the work can be formed within 10% of the intended shape, annealed, pickled, and then given the final forming.

**Solution-annealed products** are usually soft enough to permit mild forming. If the solution-annealed alloy is not soft enough for the forming operation, an annealing treatment must be used that will remove the effects of cold work and dissolve the age-hardening and other secondary phases. Some control of grain size is sacrificed, but if cooling from the annealing temperature is very rapid, the age-hardening elements will remain in solution. Further annealing after forming can be done at a lower temperature to decrease the risk of critical grain growth. Several process anneals may be required in severe forming, but the high-temperature anneal need not be repeated. Annealing should be performed at a temperature that produces optimal ductility for the specific metal, as shown in the following example.

**Example 1: Change in Heat Treatment to Eliminate Cracking.** A large manifold was made by welding together two drawn halves into

a doughnut shape. Each half was drawn to a depth of 125 mm (5 in.) from 6.35 mm (0.25 in.) thick alloy 41 that had been solution treated at 1175 °C (2150 °F) and water quenched. Drawing of the plate stock on a 31,000 N (7000 tonf) drop hammer produced severe work hardening, and cracking occurred frequently. To eliminate the cracking, forming was done in three steps, and the parts were annealed at 1080 °C (1975 °F) before the second and the third step.

The forming characteristics of the alloy 41 plate were greatly improved by modifying the solution treatment. The revised treatment consisted of first soaking the alloy at 540 °C (1000 °F), transferring it to a gantry furnace, and holding it at 1080 °C (1975 °F) for 30 min. The work was then lowered rapidly through the bottom of the furnace into a salt bath at 205 to 260 °C (400 to 500 °F). Thus, the elapsed time between leaving the high-temperature zone and entering the quench was kept to 4 or 5 s, the alloy was in the precipitation range, 595 to 1010 °C (1100 to 1850 °F) for a minimum time, and minimum hardness (16 to 21 HRC) was obtained. The salt bath provided a more uniform quench and a more ductile alloy than the original water quench. The improved ductility of the alloy allowed forming of the manifold halves in two operations.

## Formability

Formability refers to the ease with which sheet metal can be formed. Material formability is difficult to measure because there is no single index for predicting specific material formability for all processing conditions. The deformation modes in the forming of most sheet metal components are complex and consist of bending, unbending, stretching, and deep drawing. Forming technology depends a great deal on practical experience. Material characteristics such as tensile ductility, strain-hardening exponent, and anisotropy parameters can act as guides to the nature of formability and are useful for comparing materials.

In any forming operation, the useful ductility of material is that amount up to the point of necking. Greater ductility at peak load and a large separation between yield and tensile

strengths are desirable. A measure of stretchability is provided by the strain-hardening exponent ( $n$ -value). Plastic deformation in a tensile test is most commonly related to true stress in the following manner:

$$\sigma = K\epsilon^n \quad (\text{Eq 1})$$

where  $K$  is the strength constant,  $\sigma$  is true stress,  $\epsilon$  is true strain, and  $n$  is the strain-hardening coefficient.

Most nickel and cobalt alloys possess  $n$ -values between 0.35 and 0.5; a high strain-hardening capacity results in spreading the strain away from any local region in the presence of a stress gradient.

The rolling and rerolling of a metal during its manufacture may align individual grains in the sheet. This crystallographic texture imparts anisotropic plastic properties to the sheet. Depending on the alloy and processing temperatures, recrystallization during annealing will tend to restore the random grain orientation and resultant plastic isotropy. The plastic strain ratio  $r$  (the ratio of the width strain to thickness strain in a uniaxial tensile test) is a measure of normal anisotropy, that is, the variation of properties in the plane of the sheet relative to those perpendicular to the sheet surface. The average  $r$ -value is given by:

$$r = r_L + 2r_D + r_T/4 \quad (\text{Eq 2})$$

with the subscripts referring to the tensile test measurements made in the longitudinal (L), diagonal (D), and transverse (T) orientations of rolled sheet. The variation of the properties in the plane of the sheet is termed planar anisotropy ( $\Delta r$ ) and is given by:

$$\Delta r = r_L + r_T - 2r_D/2 \quad (\text{Eq 3})$$

For an isotropic material  $r = 1$  and  $\Delta r = 0$ . A material with a high  $r$ -value resists localized necking in the thickness direction; therefore, deep drawability is high. There are various correlations between deep drawability and  $r$ -value. Planar anisotropy causes uneven flow of metal, resulting in earing of drawn cups. Some typical forming characteristics of several heat-resistant alloys are given in Table 3.

Forming limit curves are often used to predict the formability of materials. The forming limit curve is experimentally constructed for combinations

of strain paths to describe strain to necking (or fracture). The forming limit diagrams for three nickel sheet alloys are given in Ref 9. The effect of small changes in the carbon and niobium content on the formability of alloy 718 is also presented in this article. More information on formability testing is available in the article "Formability Testing of Sheet Metals" in this Volume.

**Effect of Rolling Direction on Formability.** Depending on the size, amount, and dispersion of secondary phases, the age-hardenable alloys show greater directional effects than non-age-hardenable alloys. However, vacuum melting and solution annealing serve to reduce directional effects (anisotropy). Vacuum melting increases the cleanliness of the metal, reducing the number of nitride and carbide precipitates that can reduce ductility and formability. Solution annealing dissolves the precipitated phases and also recrystallizes the cold-worked structure. As shown by data for press-brake bending in Fig. 3, directional effects contribute erratically to cracking and surface defects. The following example shows how directionality seriously affected the forming characteristics of iron-base alloy A-286 (UNS S66286).

**Example 2: Effect of Directionality in Bulging A-286.** A contoured exhaust cone (Fig. 4a) was made by cutting a flat blank from mill-annealed A-286 sheet, rolling and welding a cone from the blank, and then bulging the cone into final shape. Developed blanks for two cones were cut from one sheared rectangle (Fig. 4b) with little waste of stock.

Several lots of A-286 produced good parts, but one lot of material cracked in bulging. As shown in Fig. 4(a), cracks occurred in the cone adjacent to the weld at the location where the forming stresses were perpendicular to the rolling direction (which was also the direction of minimum elongation). The tensile elongations of the good and inferior lots of A-286 were compared parallel and perpendicular to the rolling direction (Table 4). The inferior lot showed substantially greater difference in elongation between the two test directions.

**Fig. 3** Effect of forming direction relative to rolling direction on the formability of alloy 41 sheet 0.5 to 4.75 mm (0.02 to 0.187 in.) thick in press-brake bending

**Table 3** Forming characteristics of selected heat-resistant alloys

(a)  $r$ , plastic strain ratio;  $\Delta r$ , planar anisotropy. Source: Ref 7, 8

Annealing the welded cones before bulging reduced the number of cracked cones, but not by a satisfactory percentage. A higher percentage of acceptable cones resulted when the blanks were cut with their edges oriented to the rolling direction, as shown in Fig. 4(c). Cones made from these blanks had less abrupt change in the forming direction relative to rolling direction on each side of the weld, and the forming stresses were never perpendicular to the rolling direction; however, there was more scrap material from cutting the blank. When a revision of production techniques at the mill reduced the elongation difference in the two directions of stress, it was possible to use the more economical blank layout shown in Fig. 4(b).

**Speed of Forming.** The speed at which a metal is deformed affects its formability. In general, each metal has a critical speed of forming. In some cases, the ductility increases until this critical speed is reached, after which it decreases sharply with increasing speed, as indicated by the curve in Fig. 5. This curve has a plateau of maximum strain where ductility is greatest. This plateau seems to be broad for most nickel and cobalt alloys. The breadth of the plateau depends on the use of biaxial or triaxial loading of the material during forming. Table 5 recommends forming speeds for three alloys and three forming operations.

## Galling

**Nickel Alloys.** Because nickel alloys do not readily develop an oxide film that presents a barrier to diffusion bonding, they cold weld

**Fig. 4** Alloy A-286 exhaust cone that cracked in bulge forming, and the two layouts used in cutting the cone blank from 1.0 to 1.3 mm (0.04 to 0.05 in.) thick sheet

**Fig. 5** Effect of forming speed on ductility. fps, feet per second. Source: Ref 10

(gall) easily to materials of similar atomic diameter. When a cold weld is formed, the high shear strength and ductility of the alloys prevent the weld from being easily broken. For these reasons, the coefficient of friction between nickel alloys and other metals, including most die materials, is usually high.

Alloying with highly reactive elements that readily form oxide films, such as chromium, reduces the galling, or cold welding, propensity of nickel alloys. Accordingly, the nickel-chromium and nickel-iron-chromium alloys are less likely to gall than are the nickel and nickel-copper alloys. However, chromium oxide films are thin and brittle and provide only limited protection because they are easily broken when the substrate is deformed. The use of heavy-duty lubricants minimizes galling in most cold forming processes.

**Cobalt Alloys.** In situations where oxides cannot prevent intimate metal-to-metal contact, the cobalt alloys are well known for their resistance to galling, especially when self-mated. This attribute is related to their response to mechanical stress. It is believed that their low stacking fault energies, and their tendencies to transform (from face-centered cubic to hexagonal close-packed) and to twin, limit the depths affected and allow easy shear of surface layers.

## Lubricants

Heavy-duty lubricants are required on nickel alloys and cobalt alloys for most cold forming operations. Although zinc-, sulfur-, and chlorine-containing additives can improve lubricants, they can also have harmful effects if not completely removed after forming. Sulfur and zinc will embrittle nickel alloys at elevated temperatures such as may be encountered in annealing or age hardening, and chlorine can cause pitting of the alloys after long exposure. Although sulfurized and chlorinated lubricants can be used if the work is carefully cleaned with a

degreaser or an alkaline cleaner, they should not be used if any difficulty is anticipated in cleaning the formed part. Molybdenum disulfide is seldom recommended for use with nickel alloys because removal is difficult. Work that has been formed in zinc alloy dies should be flash-pickled in nitric acid before heat treatment to prevent the possibility of zinc embrittlement.

**Pigmented oils and greases** should be selected with care, because the pigment may be white lead (lead carbonate), zinc oxide, or similar metallic compounds with low melting points. These elements can embrittle nickel alloys if the compounds are left on the metal during heat treatment. Inert fillers such as talc can be used safely.

**Metallic coatings** such as copper offer the maximum film strength for a lubricant. Because application and removal are expensive, metallic coatings are used as lubricants only in severe cold forming operations, and then only when they can be properly removed.

**Ordinary petroleum greases** are seldom used in forming nickel alloys, because they have neither the film strength indicated by their viscosity nor a strong polar attraction for metals to keep them from breaking down during the forming process.

**Phosphates** do not form usable surface compounds on nickel alloys and cannot be used as lubricant carriers.

**Mild forming operations** requiring less than a 10% reduction can usually be accomplished successfully with unpigmented mineral oils and greases. Polar lubricants, such as lard oil and castor oil, are preferred for mild forming. They will usually produce acceptable results and are easily removed.

Some lubrication is usually required for optimal results in drawing, stretch forming, or spinning. Lubrication is seldom needed for the press-brake forming of V-bends but will greatly improve results if a square punch is used. For more severe forming, metallic soaps or extreme-pressure (EP) lubricants, such as chlorinated, sulfochlorinated, or sulfurized oils or waxes, are recommended. They can be pigmented with a material such as mica for extremely severe forming.

Lubricants used for spinning operations must cling tenaciously; otherwise, they will be thrown off the workpiece by centrifugal force. Metallic soap or wax applied to the workpiece before spinning is usually satisfactory. Sulfurized and chlorinated lubricants are not recommended for

**Table 4** Elongation differences in alloy A-286 sheet

Test direction with respect to rolling	Elongation, %	
	Good	Inferior
Perpendicular	41	43.5
Parallel	38.5	37.2
Difference	2.5	6.3

**Table 5** Recommended forming speeds for selected heat-resistant alloys

Alloy		Forming speed for:					
		Tensile forming(a)		Bulge forming(a)		Draw forming	
		m/s	ft/s	m/s	ft/s	m/s	ft/s

use in spinning, because this operation may burnish the lubricant into the surface of the metal. In power spinning, a coolant should also be used during the process (see the article "Spinning" in this Volume).

Occasionally, it is advantageous to use two kinds of lubricant in the same operation. In one stretch forming application, the strain at the middle of the work was 3 to 4%, but near the ends, where the metal pulled tangentially to the die, the strain was 10 to 12%. A light coat of thin oil was adequate for most of the work, but an EP lubricant was used at the ends. More information on lubricants for sheet forming is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

## Tools and Equipment

Nickel and cobalt alloys do not require special equipment for cold forming. However, the physical and mechanical properties of these materials frequently necessitate modification of tools and dies used for cold forming other metals. These modifications are discussed in this section. Information applying to specific forming operations is presented in the sections covering those operations.

Few nickel and cobalt alloys are used in applications requiring large quantities that warrant the use of high-production methods and tools. Because only a few to a few hundred parts are needed, methods requiring minimal tooling, such as press-brake forming, drop-hammer forming, spinning, and explosive forming, have been used more than other methods. Presses or other machines are the same as those used for forming steel, but because nickel and cobalt alloys have higher yield strengths and strain-hardening rates, they require stronger and harder dies and more powerful forming equipment than do low-carbon steels. Generally, 30 to 50% more power is required for nickel alloys than is needed for low-carbon steel. High-cobalt or -tungsten alloys may require 50 to 100% more power than low-carbon steels.

**Die materials** used in forming austenitic stainless steels (see the article "Forming of Stainless Steel" in this Volume) are suitable for similar operations on nickel alloys. Soft die materials such as aluminum bronze, nickel-aluminum bronze, and zinc alloys are used when superior surface finishes are desired. These materials, however, have a relatively short service life. Parts formed with zinc alloy dies should be flash-pickled in dilute nitric acid to remove any traces of zinc picked up from the dies during forming. Zinc can cause embrittlement of nickel alloys during heat treatment or high-temperature service. For similar reasons, parts formed with brass or bronze dies should be pickled if the dies impart a bronze color to the workpiece.

Cast iron has proved adequate and nongalling for many low-production forming tools. If a heat-treatable grade of iron is used, anticipated areas of high wear can be locally hardened. Steel dies,

punches, or mandrels can be plated with approximately 5 to 13  $\mu\text{m}$  (0.2 to 0.5 mil) of chromium in order to minimize adherence.

**Tool Design.** Because nickel alloys are likely to gall, and because of the high pressures developed in forming, tooling should be designed with liberal radii, fillets, and clearances. The radii and clearances used in the cold forming of nickel alloys are usually larger than those for brass and low-carbon steel and approximately equal to those for the austenitic stainless steels.

**Equipment Operation.** The strain-rate sensitivity and frictional characteristics of nickel alloys dictate that all forming operations be performed at relatively slow speeds. For instance, the slide speed in shearing, deep drawing, and press-brake bending is usually 9 to 15 m/min (30 to 50 ft/min). Cold heading, piercing, and similar operations are normally done at speeds of 60 to 100 strokes per minute.

## Shearing, Blanking, and Piercing

The optimal temper of nickel alloys for shearing, blanking, and piercing varies from skin hard to full hard, depending on the alloy and thickness. For instance, thin strip nickel 200 and the N100 alloys should be blanked in full-hard temper for maximum die life and minimum edge burr, but alloy 600 (UNS N06600) usually gives best results in skin-hard temper. Annealed temper is usually suitable for blanking of the precipitation-hardenable alloys such as alloy X-750 (UNS N07750).

Punch-to-die clearance per side should be 3 to 5% of stock thickness for thin material and 5 to 10% of stock thickness for thick ( $\geq 3.2$  mm, or  $\frac{1}{8}$  in.) material. The clearance between the punch and the stripper plate should be as small as is practical.

Shears should have a low-carbon steel rating of 50% greater than the size of the nickel alloy material to be sheared. For example, a shear with a low-carbon steel rating of 9.5 mm ( $\frac{3}{8}$  in.) should be used to cut 6.4 mm ( $\frac{1}{4}$  in.) thick alloy 400 (UNS N04400) plate.

**Lubricants** are not usually used in shearing but should be used in blanking and piercing. A light mineral oil fortified with lard oil can be used for material less than 3.2 mm ( $\frac{1}{8}$  in.) thick. Heavier sulfurized oil should be used for material that is thicker than 3.2 mm ( $\frac{1}{8}$  in.). If a sulfurized lubricant is used during blanking or piercing, the part should be cleaned thoroughly prior to heat treatment or exposure to elevated temperatures.

**Procedure.** In piercing, the minimum hole diameter is usually equal to or greater than the thickness of the material, depending on the thickness, temper, and specific alloy. Minimum hole diameters for given thicknesses of alloys 200, 400, and 600 are given in Table 6. Hole diameters equal to the thickness of the sheet have been produced in material as thin as 0.46 mm (0.018 in.), but only after considerable experience and with proper equipment.

The softer alloys, such as nickel 200, have greater impact strength than do the harder, chromium-containing alloys. Consequently, the softer alloys are more sensitive to the condition of dies and equipment. Shear knives may penetrate 65 to 75% of the material thickness before separation occurs in shearing nickel 200, whereas penetration may be only 20 to 30% in shearing the harder alloys.

Laboratory tests have indicated that the shear strength of nickel alloys in double shear averages approximately 65% of the tensile strength. However, these values were obtained under essentially ideal conditions using laboratory testing equipment with sharp edges and controlled clearances. Shear loads on nickel alloys ranged from 113 to 131% of those for low-carbon steel in production shearing, based on tests using a power shear with a rake of 31 mm/m ( $\frac{3}{8}$  in./ft) of blade length. More information on shearing is available in the article "Shearing of Sheet, Strip, and Plate" in this Volume.

**Example 3: Forming and Slotting of Alloy X.** The 88 flutes in the workpiece shown in Fig. 6 were finish formed and slotted one at a time with hand indexing in a 450 kN (50 tonf) mechanical press at the rate of one piece every 15 min, including setup. Slots were required to be within 0.5 mm (0.02 in.) of true position. The work metal was 1 to 1.1 mm (0.04 to 0.044 in.) alloy X sheet. Before the mechanical press operations, the sheet had been formed by a rubber-diaphragm process, electrolytically cleaned, annealed to 74.5 to 81.5 HR30T hardness, pickled, restruck in the forming press, and trimmed. The flutes were partially formed in this series of operations.

In choosing a method of finish forming, it was decided that the only way to form the flutes to the required shape was with a solid tool. The rubber-diaphragm forming process, however, was the best way to form the main contours of the part. The flutes could not be fully formed by a conventional die alone, because the percentage elongation exceeded the limits for alloy X (38 to 42% elongation in 50 mm, or 2 in.). By making use of the natural tendency of the blank to form wrinkles, the flutes were preformed during rubber-diaphragm forming. Although pressures were only enough to form them 75% complete, the amount of elongation needed in the final die-forming operation was lowered, and definite locations for flutes were provided. As a result, each flute could be produced in one stroke of the mechanical press. The tooling (Fig. 6, right side) consisted of a die and a cam-actuated punch of high-carbon, high-chromium tool steel hardened

**Table 6 Minimum hole diameter for piercing selected nickel alloys**

Sheet thickness, <i>t</i>		Minimum hole diameter
mm	in.	
0.46–0.86	0.018–0.034	1.5 <i>t</i>
0.94–1.78	0.037–0.070	1.3 <i>t</i>
1.98–3.56	0.078–0.140	1.2 <i>t</i>
3.97	0.156	1 <i>t</i>

to 58 to 60 HRC, as well as die inserts, stripper, and cam sections of lower-alloy, air-hardening tool steel. The punch pierced the slot and flattened the bulge above the flute. The stripper formed the flute when struck by the punch holder.

## Deep Drawing

Nickel alloys can be drawn into any shape that is feasible with deep drawing steel. The physical characteristics of nickel alloys differ from those of deep drawing steel but not so much as to require different manipulation of dies for the average deep drawing operation.

Most simple shapes can be deep drawn in nickel alloys using dies and tools designed for use on steel or copper alloys. However, when intricate shapes with accurate finished dimensions are required, minor die alterations are necessary. These alterations usually involve increasing clearances and enlarging the radius of the draw ring or of the punch nose.

**Double-Action Drawing.** In drawing and redrawing of thin stock ( $\leq 1.6$  mm, or  $1/16$  in.) into cylindrical shells with no ironing, the diameter reduction should be 35 to 40% on the first operation and 15 to 25% on redraws. If the walls are held to size, the first and second operations may be the same as suggested previously, but the amount of reduction should be diminished by approximately 5% on each successive redraw.

Although reductions of up to 50% can be made in one operation, this is not advisable because of the possibility of excessive shell breakage. Also, large reductions may open the surface of the metal and cause finishing difficulty.

The number of redraws that can be made before annealing depends on the alloy being drawn. Alloys with lower work-hardening rates (Fig. 1 and 2 and Table 2) can often be redrawn more than once without an intermediate anneal. Trial runs may be needed to determine when annealing is necessary.

**Single-Action Drawing.** As with all metals, the depth to which nickel alloys can be drawn in

single-action presses without some means of blank restraint is controlled by the blank-thickness-to-diameter ratio. For single-action drawing without holddown pressure, the blank thickness should be at least 2% of the blank or workpiece diameter for reductions of up to 35%. With properly designed dies and sufficiently thick material, the reduction on the first (cupping) operation with a single-action setup may be made equal to those recommended for double-action dies—that is, 35 to 40%. Redraws should not exceed a 20% reduction.

If the shell wall is to be ironed, the increased pressure on the bottom of the shell usually necessitates a decrease in the amount of reduction to prevent shell breakage. With reductions of 5% or less, the shell wall may be thinned by as much as 30% in one draw. With medium reductions of approximately 12%, the thickness of the shell wall can be decreased by approximately 15%. If the wall is to be reduced by a large amount, the shell should first be drawn to the approximate size with little or no wall thinning and the ironing done last. If a good surface finish is desired, the final operation should have a burnishing effect with only a slight change in wall thickness.

**Clearances.** Because nickel alloys have higher strengths than do low-carbon steel of drawing quality, nickel alloys have greater resistance to the wall thinning caused by the pressure of the punch on the bottom of the shell. Consequently, greater die clearances are required than for steel if the natural flow of the metal is not to be resisted. However, the clearances required for nickel alloys are only slightly greater than those required for steel, and if dies used for steel have greater-than-minimum clearances, they are usually satisfactory for drawing nickel alloys, depending primarily on the mechanical properties of the alloy.

For ordinary deep drawing of cylindrical shells, a punch-die clearance per side of 120 to 125% of the blank thickness is sufficient and will prevent the formation of wrinkles. In the drawing of sheet thicker than 1.6 mm ( $1/16$  in.), the general practice is to have the inside diameter of the draw ring larger than the diameter of the

punch by three times the thickness of the blank (150% of stock thickness per side).

**Draw-Ring and Punch Radii.** Because nickel alloys work harden rapidly, relatively large draw-ring and punch radii should be used, especially for the early operations in a series of draws. Nickel alloys require more power to draw than do steels; consequently, the punch imposes a greater stress on the bottom corner of the shell. Small punch radii cause thinning of the shell at the line of contact, and if such a shell is further reduced, the thinned areas will appear farther up the shell wall and may result in visible necking or rupture. Also, buffing a shell having thinned areas will cause the shell wall to have a wavy appearance. For redraws, it is preferable to draw over a beveled edge and to avoid round-edged punches except for the final draw.

The draw-ring radius for a circular die is principally governed by the thickness of the material to be drawn and the amount of reduction to be made. A general rule for light-gage material is to have the draw-ring radius from 5 to 12 times the thickness of the metal. Insufficient drawing radius may result in galling and excessive thinning of the wall.

**Drawing Rectangular Shells.** As with other materials, the depth to which rectangular shapes can be drawn in nickel alloys in one operation is principally governed by the corner radius. To permit drawing to substantial depths, the corner radii should be as large as possible. Even with large corner radii, the depth of draw should be limited to from two to five times the corner radius for alloys 400, 200, and 201, and to four times the corner radius for alloy 600 and alloy 75 (UNS N06075). The permissible depth also depends on the dimensions of the shape and on whether the shape has straight or tapered sides. The depth of draw for sheet less than 0.64 mm (0.025 in.) thick should not exceed an amount equal to three times the corner radius for alloys 400, 200, and 201 and should be less than that for alloy 600.

The corner radius on the drawing edge of the die should be as large as possible—approximately four to ten times the thickness of

Fig. 6 Finish forming of flutes and piercing of slots one at a time in an alloy X workpiece using a mechanical press. Hardness of the workpiece was 74.5 to 81.5 HR30T (186 to 247 HV). Dimensions given in inches

the material. To avoid wrinkles around the top corner of the shape, it is essential that the blank not be released prematurely.

In redrawing for the purpose of sharpening the corners or smoothing out wrinkles along the sides, only a small amount of metal should be left in the corners.

Frequently, it is necessary to draw shapes on dies designed to make a deeper single draw than is practical for nickel alloys. With such dies, the general practice is to draw approximately two-thirds of the full depth, anneal the shape after this draw, and then complete the draw to full depth on the same dies. This same practice can be used to avoid wrinkling in drawing to lesser depths. More information on the deep drawing process is available in the article "Deep Drawing" in this Volume.

**Hydroforming** is also used to deep draw parts (Ref 11). A study on hydroforming of a nonsymmetric part of alloy 718 is described in Ref 12. In this study, a viscous material was used as the pressure medium. Viscous pressure forming can form deep-drawn parts with more uniform wall and less thinning than is obtainable with deep drawing dies, because the forming is done with near frictionless contact between the forming fluid and the workpiece. Hydroforming is also used to create bellows or flexible coupling out of nickel alloys. For additional information, see the article "Rubber-pad Forming and Hydroforming" in this Volume.

## Spinning

Power spinning is preferred over manual spinning for nickel alloys (see the article "Spinning" in this Volume). However, thin material, particularly alloys 200 and 400, can be manually spun with no difficulty. Table 7 gives practical limits on blank thickness for manual spinning of six nickel alloys.

**Tools.** Except for small, light shapes, the required pressure cannot be exerted with the ordinary bar or hand tool pivoted on a fixed pin. Most shapes require the use of a tool that is mechanically adapted for the application of greater force, such as a compound-lever tool or roller tools that are operated by a screw. For small jobs, a ball-bearing assembly on the end of a compound lever can be used to make a good roller tool. Roller tools should be used whenever practical in order to keep friction at a minimum and exert maximum pressure. Roller tools should

also be used to perfect contours in the spinning of press-drawn shapes.

When possible, tools used for spinning nickel alloys should be broader and flatter than those used for softer materials. The broader tool distributes plastic flow over a greater area and reduces overstraining. Except for this consideration, bar and roller tools should be designed the same as those used for spinning copper or brass.

Correct tool materials are essential for successful spinning. The most suitable material for bar tools is a highly polished, hard alloy bronze. Hardened tool steels are preferred for roller and beading tools. Chromium-plated hardened tool steel is recommended, because it decreases metal pickup by the tool. Tools of common brass and carbon steel, which are used for spinning softer materials, are unsatisfactory for use with nickel alloys.

Rotary cutting shears are preferred for edge trimming. If rotary shears are not available, hand trimming bars hard faced with a cobalt alloy may be used, but the trimming speed must be reduced. Hand trimming bars should be ground so that they have a back-rake angle of 15° to 20° from the cutting edge, and the edge must be kept sharp. A tool shaped like a thread-cutting lathe tool can be used for trimming. This tool also has a back rake from the cutting edge. With this type of tool, the material is not sheared off the edge; instead, the tool is fed into the side of the workpiece, and a narrow ring is cut from the edge. The workpiece should be supported at the back during all trimming operation.

**Mandrels.** Hardened cast iron and steel mandrels give longer life and better results than softer materials such as wood. Hard maple or birch mandrels may be used for intermediate operations if production quantities are small and tolerances are liberal.

Spinning nickel alloys over mandrels that are the same as those used for copper alloys will not necessarily result in spun shapes of exactly the same dimensions as those of the softer metal. Because of the greater springback, most nickel alloy shapes will have slightly larger peripheries than those of softer metals spun over the same mandrel.

**Lubricants.** Heavy-bodied, solid lubricants, such as yellow laundry soap, beeswax, and tallow, are recommended for spinning. These lubricants can be manually applied to the blank as it rotates. Blanks can be electroplated with 5 to 18  $\mu\text{m}$  (0.2 to 0.7 mil) of copper to improve lubrication on difficult shapes.

**Procedure.** The spinning procedures for nickel alloys are essentially the same as that used for other metals (see the article "Spinning" in this Volume). Generally, when planning a spinning sequence for alloy 400, an increase in height of 25 to 38 mm (1 to 1½ in.) on the article being spun constitutes an operation if spinning is being done with a bar tool. Approximately twice that depth per operation may be obtained with a compound-lever or roller tool. The workpiece

should be trimmed and annealed before it is spun to greater depths.

A hard-surfaced mandrel should be provided for each operation so that the metal can always be pushed firmly against the surface of the mandrel. This procedure keeps the workpiece surface smooth and dense and ensures the best results in annealing. With an insufficient number of intermediate mandrels, the material is subjected to an excessive amount of cold working. This may result in either spinning a buckle into the material or formation of a pebbled surface. It is virtually impossible to smooth out the former by additional cold work, or to correct the latter by annealing.

Figure 7 illustrates the number of mandrels and annealing operations necessary for spinning deep cups from 0.94 mm (0.037 in.) thick alloy 200, 400, and 600 blanks using hand tools. Figure 7 also shows the amount of forming that can be done before annealing and between intermediate anneals. The spinnability of other alloys can be estimated from their relative work-hardening rates (Fig. 1 and 2) and from their tensile properties.

In spinning, the optimal speed of the rotating blank is governed by its diameter and thickness. Small, thin blanks can be spun at greater speeds than larger or thicker pieces. Nickel alloys are often spun at speeds of one-half to three-fourths those normally used in spinning the same shape from softer metals. Lathe speeds of 250 to 1000 rpm are usually satisfactory. Trimming speeds, by necessity, must be slow and are ordinarily done at the minimum speed of the lathe.

**Example 4: Forming Alloy A-286 Tube by Spinning.** The tube shown at the top of Fig. 8 was backward spun from a roll forging that had been solution annealed at 980 °C (1800 °F). A starting groove had been machined into the tube in a previous operation. Spinning was performed in three passes on a machine capable of spinning a part 1065 mm (42 in.) in diameter and 1270 mm (50 in.) in length. Backward spinning was used in preference to forward spinning because:

- The finished workpiece was longer than the mandrel.
- Forward spinning would have required a change in workpiece design to permit hooking over the mandrel.
- Backward spinning is faster than forward spinning.

For convenience, the flanges were left at both ends and trimmed off later. The flanges prevented bell-mouthing and permitted trimming of the portions likely to have small radial cracks.

## Explosive Forming

Explosive forming has been used extensively to form sheet metal parts. Part tolerances

**Table 7 Minimum blank hardness and thickness for manual spinning of nickel alloys**

Alloy	Minimum hardness, HRB	Minimum thickness	
		mm	in.
Nickel 200	64	1.57	0.062
Nickel 201	55	1.98	0.078
Alloy 400	68	1.27	0.050
Alloy 600	80	0.94	0.037
Alloy X-750	94	0.94	0.037

**Fig. 8** Backward spinning of alloy A-286 roll-forged tube (hardness, 203 HV max). Dimensions given in inches

**Fig. 9** Explosive forming of a case from 1.5 mm (0.060 in.) thick alloy A-286 sheet. Dimensions given in inches

**Fig. 10** Alloy 718 flame deflector formed from sheet 1.8 mm (0.072 in.) thick by explosive forming in three successive charges. Dimensions given in inches

obtainable from explosive forming can range from  $\pm 0.025$  mm (0.001 in.) to  $\pm 0.25$  mm (0.01 in.) depending on the size and complexity of the part. The article "High-Velocity Metal Forming" in this Volume describes the technique and capabilities of this method. Some examples of explosive forming to create parts from nickel and cobalt alloys are given as follows.

**Safety in Explosive Forming.** Operations involving explosives and pressure vessels are governed by state, county, and municipal regulations. The requirements and restrictions of these regulations should be taken into account in tool design and operational setup for explosive forming.

**Example 5: Explosive Forming of Alloy A-286.** A tubular workpiece was explosively formed inside a die (Fig. 9) to produce a part with an internal flange. If this part had been produced by other methods, such a flange would have had to be welded on. The A-286 sheet was rolled into a round cylinder 405 mm (16 in.) in diameter, welded, solution treated, and descaled. Tolerance on the diameter was  $\pm 0.75$  mm ( $\pm 0.03$  in.).

Gel dynamite was the explosive used. Six shots were used to form the workpiece. For shots 1 and 2, 15 g of explosive was used; for shot 3, 18 g; for shot 4, 20 g; and for shots 5 and 6, 25 g. After three shots, the workpiece was solution annealed and descaled.

**Example 6: Explosive Forming of Alloy 718.** Fully annealed alloy 718 (UNS N07718) sheet was used to make the flame deflector shown in Fig. 10. The sheet was rolled onto a cylinder, with the grain direction at right angles to the long axis of the cylinder. A 115 mm (4.5 in.) outside diameter by 815 mm (32 in.) long tube was gas tungsten arc welded from the cylinder using alloy 41 filler rod. The weld was made flush on the inside, and the outside was ground flush to  $+0.13$  mm ( $+0.005$  in.). The tube was spun to the dimensions shown in Fig. 10, fully annealed at  $955^\circ\text{C}$  ( $1750^\circ\text{F}$ ), and grit blasted. An outstanding characteristic of this alloy is its slow response to age hardening, which enables it to be welded and annealed with no spontaneous hardening unless cooled slowly. Explosive forming of the flame deflector was accomplished by three successive charges in a

split die, and the workpiece was fully annealed after explosive forming.

**Example 7: Explosive Forming of Alloy 25.** Figure 11 shows the setup used for the explosive forming of a tail-pipe ball from alloy 25 sheet. The sheet was gas tungsten arc welded (butt) into a cylinder, and the shape was formed by three explosive charges. No annealing was done between welding and the first two shots of explosive forming, but after the first two shots (50 g of dynamite for each), the workpiece was withdrawn from the die, annealed at  $1175^\circ\text{C}$  ( $2150^\circ\text{F}$ ), and descaled. The workpiece was returned to the die for further forming. The third explosive charge used 62 g of dynamite. Tolerance on diameters was maintained within  $\pm 0.25$  mm ( $\pm 0.01$  in.).

Explosive forming was preferred over forming on an expanding mandrel, because the mandrel left flats on the wall of the workpiece, and explosive forming did not.

**Example 8: Alloy N-155 Exit Nozzle Produced by Tube Spinning and Explosive Forming.** The exit nozzle shown in Fig. 12 was produced from fully annealed 3.4 mm (0.135 in.) thick alloy N-155 sheet. The sheet was rolled into a cylinder, with grain direction at right angles to the long axis, and was gas tungsten arc welded. The weld was ground flush on both the inside and outside, after which the cylinder was tube spun to the various wall thicknesses shown in Fig. 12. The workpiece was then placed in a die and explosively formed to the shape shown at right in Fig. 12.

The underwater explosive-forming technique was used, with a vacuum of 3 kPa (0.03 atm) between the workpiece and the die. The explosive charge was equal to 620 g of TNT and was placed at an average distance of 190 mm (7½ in.) from the workpiece walls. The first shot produced approximately 90% of the final shape. A second shot, using the same size charge, completed the workpiece, after which it was fully annealed.

## Bending Sheet, Strip, and Plate

Table 8 lists minimum bend diameters for hot-rolled and annealed nickel alloy sheet, plate, and strip. In compiling these data, a sample was

judged to have passed the 180° bend test if its surface showed no ductile fracturing. Because of the effects of various surface conditions and heat treatments on bending, the data in Table 8 should be regarded as general guidelines. Many of the materials can be bent in stages to tighter radii than those suggested, provided the initial bend is not too severe.

The importance of surface condition is demonstrated by the alloys from which scale or oxides must be removed to ensure successful bending. As indicated in Table 8, scale can be removed either by chemical or mechanical means, depending on the alloy.

## Expanding/Tube Forming

Nickel alloy tubing can be expanded into tube sheets for heat exchanger applications by any conventional method. The oversize allowance on tube sheet holes to the nominal outside diameter of the tube should be kept to a minimum. The tube sheet hole should be 0.10 to 0.20 mm (0.004 to 0.008 in.) larger than the nominal outside diameter of the tube for tubing less than 38 mm (1½ in.) in outside diameter. For tubing 38 mm (1½ in.) or larger in outside diameter, the oversize allowance should be 0.23 to 0.25 mm (0.009 to 0.010 in.).

**Procedure.** Expanding may be done by drifting with sectional expanders or by rolling with three-roll expanders. Three-roll expanders are preferred. The ends of rolled-in tubing are flared in the conventional manner.

The tube sheet hole and both the outside and inside surfaces of the tube must be free of all foreign matter such as oxides, dirt, and oil. The ends of the tube should also be deburred before rolling. Lubrication should be provided between the rollers of the tool and the inside surface of the tube. Any sulfur-free mineral oil or lard oil,

either diluted or straight, can be used. Lubricants that contain embrittling or contaminating elements such as sulfur, zinc, or lead should be avoided, because of the difficulty in cleaning the finished assembly.

Controlled rolling equipment should be used to prevent overexpanding, which may distort the tube sheet and deform the tube sheet ligaments, causing loose-fitting tubes. This is particularly true when the tube has a higher hardness than the tube sheet or a significantly higher rate of work hardening.

**Temper.** The tube sheet should be harder than the tube being rolled into it. Otherwise, springback in the tube may be greater than in the tube sheet, causing a gap between the two when the expanding tool is removed. For this reason, tube sheets are usually supplied in the as-rolled or as-forged temper, and tube is supplied in the annealed temper. The need for the tube sheet to be harder than the tube is greatest when the thickness of the tube sheet is less than the outside diameter of the tube, and when the center-to-center spacing of the tubes (tube pitch) is less than 1¼ times the outside diameter of the tube or the outside diameter plus 6.4 mm (¼ in.), whichever is greater.

Stress-relieved tubing may be slightly harder than the tube sheet but can be expanded to form a satisfactory connection if greater care is exercised in expanding. For greater assurance of pressure tightness, a seal weld may be placed around the end of the tube after expanding. The stress-relieved temper is suitable for either welding or silver brazing.

Tubing in the annealed condition is used when optimal rolling or expanding characteristics are desired or for severe cold bending and flaring.

**Example 9: Manufacture of Bellows from Nickel Alloys.** Bellows manufacturing is a good illustration of the excellent fabricability of

**Fig. 11** Alloy 25 welded cylinder (sheet thickness, 1.7 mm, or 0.066 in.) in position for explosive forming. Dimensions given in inches

(a) Bend test performed according to ASTM E 290 with a guided bend jig as described in ASTM E 190. (b) For plate, sheared edges were ground or machined. (c) Successful bending depended on surface condition of the samples, in particular to freedom from oxidation. (d) Samples were descaled.

many corrosion-resistant and high-temperature-resistant nickel alloys. Nickel alloy bellows are used in expansion joints and flexible couplings to accommodate mechanical and thermal stresses found in many industrial, aerospace, and automotive components requiring corrosion resistance from the operating environment. Fatigue-resistant high-nickel alloys are readily cold formed into intricate bellows assemblies. Typical sizes range from 6.5 cm (2.5 in.) diameter in automotive and aerospace applications to 100 cm (3 ft) in diameter in chemical and refining industry applications.

Coiled strip is the typical starting material for bellows. The strip is fed into a roll former to make the proper-diameter tube, which is then welded longitudinally with an automatic gas tungsten arc weld without a filler metal. During this autogenous weld, inert gas is supplied continuously to both sides of the weld to reduce the formation of deleterious oxides, nitrides, and carbides. After the welding is complete, the weld is planished between hard rollers to flatten the weld profile and increase the strength of the weld joint. Heat treatment of nickel alloys is typically not required prior to or after bellows forming. Once the welding and planishing are complete, the tube is trimmed to length for forming.

The most common methods for forming bellows are punch forming, roll forming, and hydraulic forming. In expanding mandrel or punch forming (Fig. 13), the welded tube is located around a flat circular die set that consists of several pie-shaped segments. The segments are forced radially outward with a cone-shaped ram, thereby expanding the tube to form a convolution.

In roll forming (Fig. 14), the welded tube is located over a flat circular inner roller that is forced radially outward between two outer rollers while the tube is rotating. The convolutions are formed one at a time in both punch forming and roll forming.

In hydraulic forming (Fig. 15), the welded tube is located inside of external dies or forming rings. The tube is internally pressurized, forcing the nickel alloy material to expand outward between the rings. As forming progresses, the rings move together. In hydraulic forming, several of the convolutions are formed at one time.

Once all of the convolutions are formed, excess material is trimmed from the bellows tangents, and the bellows are nondestructively tested to ensure that the part is free of defects. After inspection is complete, the parts are ready for installation.

**Example 10: Superplastic Forming of Alloy 718.** *Superplasticity* is a term used to describe large elongations in polycrystalline material, typically several hundred percent, obtained during tensile loading (see the article "Superplastic Sheet Forming" in this Volume). Generally, materials exhibiting superplasticity exhibit low resistance to plastic flow in specific temperature and strain-rate regions. The cost savings in producing superplastic parts can be considerable; the complex parts formed using superplastic

forming technology enable the elimination of extensive welding or other joining methods in addition to the lowering of inventory of parts and a simplification of the manufacturing process.

The high-strength nickel alloys used in the construction of commercial and military aircraft components are superplastically formed on a commercial basis. One noteworthy example is

alloy 718 (UNS N07718) sheet produced to a grain size of ASTM 10 or finer using rigorous controls of composition, melt practice, and rolling conditions. The resulting sheet product is provided as UNS N07719 to AMS 5950. The controlled production practice provides a sheet product that enables the product to have the two essential characteristics that make the alloy

# Forming of Refractory Metals

Revised by Louis E. Huber, Jr., Cabot Supermetals Corporation  
Christopher A. Michaluk, Michaluk and Associates

REFRACTORY METALS are generally worked in small quantities. Production rates are low, each piece is handled separately, and the forming process is closely controlled.

Table 1 shows the composition of refractory alloys available as sheet. Typical conditions for bending 0.5 to 1.3 mm (0.020 to 0.050 in.) thick sheet are given in Table 2. Tensile-forming parameters for sheet materials are summarized in Table 3.

## Formability

Niobium and tantalum alloys are usually formed at room temperature in the annealed (recrystallized) condition, although the stress-relieved alloys are sufficiently ductile for most forming operations. Work hardening, especially of the stronger alloys, often necessitates annealing after severe forming.

Strong alloys of niobium and tantalum, which are made in limited quantity, are not listed in

Table 1. These alloys have varying degrees of brittleness at low temperature but can be formed by the same procedures used for molybdenum.

Molybdenum and tungsten are more difficult to form than niobium and tantalum, but if they are heated and certain precautions are taken, even complex parts can be formed. The greatest difficulty in forming these metals is their tendency toward brittle fracture (cracks and ruptures that occur with little or no plastic deformation) and delamination (a type of brittle behavior that produces cracks or ruptures parallel to the plane of the sheet). Tungsten can be hot formed only; it is brittle at room temperature.

At slow strain rates in tension and in bending, molybdenum and titanium-zirconium-molybdenum (TZM) alloys are ductile at room temperature, becoming brittle at lower temperatures. However, because of the high variable strain rates and triaxial stresses produced in the usual forming processes, these metals are usually hot formed in order to decrease the probability of brittle fracture. Molybdenum and tungsten blanks must have prepared edges to prevent cracking and splitting during forming.

Molybdenum and tungsten are generally supplied in the stress-relieved condition. Recrystallization increases the ductile-to-brittle transition temperature.

**Effects of Composition on Embrittlement.** Niobium and tantalum are severely embrittled by oxygen, nitrogen, and hydrogen on exposures at temperatures above approximately 300 °C (570 °F). However, the usual melting and processing techniques keep the metals pure enough for good formability.

Some niobium alloys are more resistant to grain growth at high temperature than high-purity niobium. Alloys such as Nb-1Zr and C-103 are dispersion-strengthened materials that resist grain growth at high temperature. These alloys have fine grain structure and elongate uniformly for forming and drawing operations.

**Surface Contamination.** The most common causes of surface contamination are failure to clean the surface properly and failure to provide the proper atmosphere in heat treatment. Niobium and tantalum are usually acid pickled, and they are heat treated in a vacuum or an inert gas atmosphere. Additional information on the heat treating of refractory metals is available in the article "Heat Treating of Refractory Metals and Alloys" in *Heat Treating*, Volume 4 of *ASM Handbook*, 1991.

Generally, the high-strength alloys are more severely embrittled by surface contamination than the lower-strength alloys. Molybdenum and tungsten are much less susceptible to surface

contamination by oxygen and nitrogen than niobium and tantalum.

## Factors That Affect Mechanical Properties

The major variables that affect mechanical properties and formability are working temperature, temperature of anneals between operations, percentage of reduction after the final anneal, and temperature of final heat treatment.

**Rolling.** Refractory metal sheet is generally made by hot forging or extruding billets to make sheet bars, which are rolled to sheet at high temperature. The final rolling of niobium and tantalum alloys is done below 540 °C (1000 °F), often at room temperature. The cold-worked sheet is given a final recrystallization anneal to improve formability and ductility. The finish rolling of molybdenum and tungsten is done at high temperature, and final heat treatment is usually for stress relief only. Cross-rolled sheet is generally more formable, because cross rolling promotes planar isotropy desired for uniform deformation.

**Heat Treatment.** In the annealed (recrystallized) condition and in the ductile range, refractory metals behave much like low-carbon or interstitial-free steels. For example, recrystallized tungsten, although brittle at low temperature, has 35% uniform elongation and 50% total elongation at 400 °C (750 °F). Cold working strengthens molybdenum and tungsten and makes them less formable. Although molybdenum and tungsten are given a final stress relief, they retain their cold-worked structure.

Figure 1 shows the effect of heat treatment and strain hardening on the ductility and the ductile-to-brittle transition temperature range of unalloyed molybdenum. The curves in Fig. 1 show that the ductile-to-brittle transition for unalloyed molybdenum is between -18 and -45 °C (0 and -50 °F) for the stress-relieved condition, between 25 and -25 °C (80 and -10 °F) for the stretch-strained condition, and at approximately 25 °C (80 °F) for the recrystallized condition.

**Transition Temperature.** Niobium, tantalum, and their most frequently used alloys are readily formable, and they are ductile at temperatures as low as -195 °C (-320 °F). Molybdenum and TZM, in the stress-relieved condition, have transition temperatures just below room temperature. Molybdenum may fracture or delaminate at room temperature under the high deformation rates and stresses generally encountered in forming practice. Therefore, molybdenum alloys are generally formed at moderate-to-high temperatures. Stress-relieved tungsten has a transition temperature of 150 to 315 °C (300 to 600 °F), so that all forming of tungsten must be done at high temperatures.

Figure 2 shows how temperature changes the strength and elongation of a typical high-strength niobium alloy with good formability. A slight increase in temperature reduces yield strength but also reduces ductility. The ductility is

lowest at approximately 650 °C (1200 °F) and then increases with temperature. This reduced ductility is caused by strain aging, which is characteristic of body-centered cubic metals.

Figure 3 shows how temperature changes the ductility of four typical refractory metals. The ductility minimums lie between 540 and 1095 °C (1000 and 2000 °F). The tantalum and niobium alloys in Fig. 3 were annealed (recrystallized), and the molybdenum alloy and tungsten were stress relieved. Tests above 260 °C (500 °F) were conducted in a vacuum.

**Fig. 1** Effect of heat treatment and strain hardening on the ductility and ductile-to-brittle transition temperature range of unalloyed molybdenum sheet as determined in tensile tests. The ductile-to-brittle transition occurs in the temperature range in the steep portion of the ductility curves.

## Effect of Temperature on Formability

Annealed niobium and tantalum alloys are formed at room temperature. Heating these alloys would reduce their formability because of strain aging and would cause oxidation and possible surface contamination.

Tungsten is brittle at room temperature. Therefore, thin tungsten sheet is formed at 315 to 540 °C (600 to 1000 °F), and thicker sheet or complex shapes are formed at 540 to 815 °C (1000 to 1500 °F) after stress relief.

**Fig. 2** Effect of temperature on strength and elongation of vacuum-annealed (recrystallized) niobium alloy sheet

Fig. 3 Effect of temperature on the ductility of four refractory metals

Fig. 4 Effect of temperature on the formability of Mo-0.5Ti sheet as indicated by the ratio of bend radius to sheet thickness

Molybdenum and molybdenum alloys, in thin sheets, can be cold formed to some extent, but heating helps to prevent fracture and delamination. As shown in Fig. 3, the TZM alloy is most ductile at 95 °C (200 °F). Further increases in temperature lessen ductility, because of strain aging. Most molybdenum is formed at 95 to 315 °C (200 to 600 °F), but thicker metal or complex shapes are formed at 315 to 650 °C (600 to 1200 °F).

Figure 4 shows the effect of heating on the bending of TZM sheet. This material is most formable at 95 to 205 °C (200 to 400 °F). Forming at lower temperatures may crack it. In one case, two sheets of TZM required bending. One sheet shattered when formed at room temperature, but the second sheet formed well in severe forming at 150 °C (300 °F). Erickson cup ductility tests indicated the two sheets to be of equal formability at room temperature.

## Forming of Sheet

All of the common sheet-forming methods are used for refractory metals. However, the necessity of using elevated temperature in forming molybdenum and tungsten usually precludes the

stretch forming and rubber-pad forming of these two metals.

**Niobium and Tantalum.** Almost all forming of niobium and tantalum is done at room temperature using conventional tools. A backup sheet is frequently used in a press brake to reduce galling or to provide support, so that the part will more closely follow the punch radius.

Niobium alloy C-103 is more ductile than type 310 stainless steel; it can be power spun to 60% reduction and deflects the rolls only half as much as type 310 stainless. Tantalum can be spun in thicknesses as great as 15.75 mm (0.620 in.).

Tantalum, niobium, and Nb-1Zr sheet can be readily drawn into cups, tubes, or other shapes amenable to drawing methods. However, these materials exhibit a serious tendency toward galling to tool surfaces at contact pressures that are almost always exceeded in the drawing process. The tendency toward galling increases with each redraw but can be significantly reduced or eliminated through careful attention to tool geometry, material surface condition, and workpiece lubrication.

The following rules should be observed when designing parts for deep drawing in these materials:

- Parts should have uniform wall thickness.
- A 25% thinning allowance should be made on tight corners or extreme reductions in diameter; thinning can be effectively controlled through careful tool design.
- The overall length should be less than nine times the smallest diameter in most cases, unless intermediate annealing is considered.
- Bends of up to 90° can be made on inside radii of one-half the material thickness; bends over 90° should have an inside radius of at least one wall thickness.
- Resultant surface finish is a function of grain size, severity of cold working, and original surface finish; it is difficult to "iron" to improve the surface finish because of galling.

One method used to reduce galling consists of oxidizing the material surface by heating in an open furnace to temperatures as high as 650 °C (1200 °F) for tantalum or as high as 625 °C (1155 °F) for niobium or Nb-1Zr. The thickness of the oxide produced is related to the length of time at temperature and the surface condition of the material. A soak of 1 to 2 min produces a surface with greatly reduced tendency to gall. In most cases, this oxide must be removed from completed workpieces by acid etching or other means. The oxide is quite stable and is strongly abrasive to draw tooling. Serious reduction in tool life can be a problem when oxides are used.

Standard chlorinated drawing compounds are appropriate lubricants for the drawing of these materials. Spray or flood-type lubrication systems help to ensure adequate lubrication for parts requiring multiple redraws. Particular care must be taken to lubricate die surfaces, because dry spots will initiate galling.

Trimming or blanking operations should be conducted with a minimum punch-to-die clearance. This reduces metal pickup on tool surfaces. Burr-free or nearly burr-free results can be achieved.

**Molybdenum and Tungsten.** All of the common sheet-metal forming methods except rubber-pad forming and stretch forming are used for molybdenum and tungsten. These metals are formed at high temperature to prevent the cracking and delamination that occur when forming at room temperature. Stretch forming has not been successful, because of the difficulties in adapting high temperatures to the process.

Proper preparation of the edges of blanks is necessary in the forming of molybdenum and tungsten. All edges in tension during forming must be rounded or polished to prevent fracture. Shearing and sawing may cause edge cracking and delamination, which must be removed before forming.

Power and manual spinning are used extensively to work tungsten sheet. Tungsten can be power spun in machines that are capable of power spinning steel. Complex contoured or deeply recessed parts are often produced by drop hammer forming. All work is done with heated tools and with work metal temperatures ranging from 595 to 1095 °C (1100 to 2000 °F). Many failures in forming tungsten are caused by the stressing of edge defects in the starting blanks. These defects originate in sawing, shearing, or blanking and are difficult to detect visually.

Tools and workpiece blanks are heated by electrical-resistance elements, heat lamps, and gas torches. An allowance for the difference in thermal expansion between steel dies and a tungsten or molybdenum workpiece is required for all parts whose shape or dimensions will be out of tolerance because of forming at high temperature. Hot work tool steels are satisfactory die materials. A bronze facing is recommended for steel dies if galling becomes a problem. Aluminum tooling is not recommended, because of its high thermal expansion.

Localized deformation and wrinkling of complex parts formed from molybdenum and tungsten generally result from poor die design and operation. These problems can be avoided by proper die clearance, staging and contours, and mechanical support. A steel backup sheet is sometimes used to ensure that the part more closely follows the punch or to reduce galling.

## Forming of Preformed Blanks

Refractory metals that are preformed and welded into shaped blanks, cones, or cylinders can be formed by the same process used for unwelded blanks of common sheet metals. The welds must be of high quality to avoid defects or embrittlement. Chemical blanking, electrical discharge machining, abrasive cutting, and milling are preferred for making blanks. The

following sequence of operations is generally used in preforming:

- Form intermediate shape
- Weld by the gas tungsten arc method
- Grind weld flush and inspect
- Stress relieve or anneal
- Form to final shape

Weldments of molybdenum and tungsten are generally formed at temperatures 95 to 150 °C (200 to 300 °F) higher than unwelded sheet of the same metals, and the weldments are usually stress relieved before forming. In some extreme

applications, parts are stress relieved before and after welding, and after forming.

## Lubricants

The types of lubricants used in the forming of refractory metals include oils, extreme-pressure lubricants, soaps, waxes, silicones, graphite, molybdenum disulfide, copper plating, and an acrylic enamel coating made by suspending powdered copper in acrylic resin.

Ordinary oils and greases are commonly used in the forming of niobium and tantalum, because these metals are generally formed at room temperature. Petrolatum is frequently used for severe forming operations. Solid lubricants and suspensions of suitable pigments, such as molybdenum disulfide with or without colloidal graphite, are used in the hot forming of molybdenum and tungsten. Chlorinated lubricants and others that decompose upon heating to form toxic or noxious fumes must not be used without proper safety precautions.

# Forming of Titanium and Titanium Alloys

Joseph D. Beal, Rodney Boyer, and Daniel Sanders, The Boeing Company

TITANIUM AND ITS ALLOYS can be formed in standard machines to tolerances similar to those obtained in the forming of stainless steel. However, to reduce the effect of springback variation, improve accuracy, and to gain the advantage of increased ductility, the great majority of formed titanium parts are made by hot forming or by cold preforming and then hot sizing.

The following characteristics of titanium and titanium alloy sheet materials must be considered in forming:

- Notch sensitivity, which may cause cracking and tearing, especially in cold forming
- Gallling (more severe than with stainless steel)
- Relatively poor ability to shrink (a disadvantage in some flanging operations)
- Potential embrittlement from overheating and from absorption of gases, principally hydrogen and oxygen (scale and the surface layer adversely affected by the slower penetration of oxygen can be removed readily)
- Limited workability—varies with the alloy
- Higher springback than that encountered in ferrous alloys at the same strength level

However, as long as these limitations are recognized and established guidelines for hot and cold forming are followed, titanium and titanium alloys can be successfully formed into complex parts.

The mechanical properties, and therefore the formabilities, of titanium and its alloys vary widely. For example, the tensile strength of different grades of commercially pure (CP) titanium ranges from 240 to 550 MPa (35 to 80 ksi); correspondingly large differences in formability are obtainable at room temperature. The tensile strength and ductility of CP titanium are largely dependent on its oxygen content. Table 1 lists the common designations, compositions, and selected mechanical properties of some titanium alloys.

## Titanium Alloys

**Alloy Ti-6Al-4V** is the most widely used titanium alloy, accounting for approximately 60% of total titanium production. Unalloyed grades constitute approximately 20% of pro-

duction, and all other alloys make up the remaining 20%. Selection of an unalloyed grade of titanium, an  $\alpha$  or near- $\alpha$  alloy, an  $\alpha$ - $\beta$  alloy, or  $\beta$  metastable alloy depends on desired mechanical properties, forming method, service requirements, cost, and the other factors that enter into any materials selection process. The high solubility of the interstitial elements oxygen and nitrogen makes titanium rather unique among metals and creates problems that are not of concern in most other metals. For example, heating titanium in air at high temperature results not only in oxidation but also in solid-solution hardening of the surface as a result of inward diffusion of oxygen. A surface-hardened zone (alpha case) is formed. This layer is usually removed by machining or chemical milling prior to placing a part in service. The presence of this layer reduces fatigue strength and ductility.

**Commercially pure titanium** is usually selected for its excellent corrosion resistance, especially in applications in which high strength is not required. The yield strengths of CP grades (Table 1) vary from less than 170 to more than 480 MPa (25 to 70 ksi) as a result of variation in the interstitial, grain size, and impurity levels. Oxygen and iron are the primary variants in these grades; strength increases with increasing oxygen and iron contents and decreases with grain size. Grades of higher purity (lower interstitial content) are lower in strength, hardness, and transformation temperature than those higher in interstitial content.

**Alpha and Near-Alpha Alloys.** Alpha alloys that contain aluminum, tin, and/or zirconium are preferred for high-temperature and cryogenic applications. Alpha-rich alloys are generally more resistant to creep at high temperature than  $\alpha$ - $\beta$  or metastable  $\beta$  alloys. The extra-low-interstitial  $\alpha$  alloys (ELI grades) retain ductility and toughness at cryogenic temperatures, and Ti-5Al-2.5Sn-ELI has been extensively used in such applications. Unlike  $\alpha$ - $\beta$  and metastable  $\beta$  alloys,  $\alpha$  alloys cannot be strengthened by heat treatment. Generally,  $\alpha$  alloys are annealed or recrystallized to remove residual stresses induced by cold working. Alpha alloys that contain small additions of  $\beta$  stabilizers (for example, Ti-8Al-1V-1Mo or Ti-6Al-2Nb-1Ta-0.8Mo) are sometimes classed as near- $\alpha$  alloys.

Although they contain some retained  $\beta$  phase, these alloys consist primarily of  $\alpha$  and behave more like conventional  $\alpha$  alloys than  $\alpha$ - $\beta$  alloys. They can, however, be strengthened by grain size.

**Alpha-beta alloys** contain one or more  $\alpha$  stabilizers or  $\alpha$ -soluble element plus one or more  $\beta$  stabilizers. These alloys retain more  $\beta$  phase after final heat treatment than near- $\alpha$  alloys; the specific amount depends on the amount of  $\beta$  stabilizers present and on the solution heat treating temperature and time.

Alpha-beta alloys can be strengthened by solution treating and aging. Solution treating is usually done at a temperature high in the two-phase  $\alpha$ - $\beta$  field and is followed by quenching in water, oil, or other suitable quenchant. The  $\beta$  phase present at the solution-treating temperature may be retained or may be partly transformed during cooling by either martensitic transformation or nucleation and growth. The specific response depends on alloy composition, solution-treating temperature ( $\beta$ -phase composition at the solution temperature), cooling rate, and section size. Solution treatment is followed by aging, usually in the 480 to 650 °C (900 to 1200 °F) range.

Solution treating and aging can increase the strength of  $\alpha$ - $\beta$  alloys 20 to 50%, or more, over the annealed or overage condition. Response to solution treating and aging depends on section size; alloys relatively low in stabilizers (Ti-6Al-4V, for example) have poor hardenability and must be quenched rapidly to achieve significant strengthening. For Ti-6Al-4V, the cooling rate of a water quench is not rapid enough to cause significant hardening of sections thicker than approximately 25 mm (1 in.). Hardenability increases as the content of  $\beta$  stabilizers increases. It should be noted that distortion can also be experienced during the solution-treating operation. The thinner the material, the greater the distortion when using water quench. It is best to use sheet material in the annealed condition to eliminate this problem.

**Metastable beta alloys** are richer in  $\beta$ -phase stabilizers and leaner in  $\alpha$  stabilizers than  $\alpha$ - $\beta$  alloys. They are characterized by high hardenability, with  $\beta$  phase completely retained upon the air cooling of thin sections or the water quenching of thick sections. Beta alloys in sheet

form can be cold formed more readily than high-strength  $\alpha$ - $\beta$  or  $\alpha$  alloys. An example of this is the Ti-15V-3Sn-3Cr-3Al alloy, which is formed almost exclusively at room temperature. After solution treating, metastable  $\beta$  alloys are aged at temperatures of 450 to 650 °C (850 to 1200 °F) to partially transform the  $\beta$  phase to  $\alpha$ . The  $\alpha$  forms as finely dispersed particles in the retained  $\beta$  and gives strength levels comparable to or superior to those of aged  $\alpha$ - $\beta$  alloys.

In the solution-treated condition (100% retained  $\beta$ ), metastable  $\beta$  alloys have good ductility and toughness, relatively low strength, and excellent uniaxial formability. However, their formability is less for biaxial forming. Solution-treated metastable  $\beta$  alloys begin to precipitate  $\alpha$  phase at slightly elevated temperatures and are therefore generally unsuitable for elevated-temperature service without prior stabilization or overaging treatment.

## Superplastic Alloys

The workhorse superplastic titanium alloy is Ti-6Al-4V, and the state-of-the-art in titanium superplastic forming is largely based on this alloy. However, a number of titanium alloys, especially the  $\alpha$ - $\beta$  alloys, exhibit superplastic behavior. Many of these materials, such as Ti-6Al-4V, are superplastic without special processing. Table 2 gives data concerning the superplastic behavior of some titanium alloys and lists the characteristics used to describe

superplastic properties in engineering alloys: strain-rate sensitivity factor, *m*, and tensile elongation. The *m*-value is a measure of the rate of change of flow stress with strain rate; the higher the *m* value of an alloy, the greater its superplasticity. Titanium alloys that have exhibited superplasticity but are not listed in Table 2 include Ti-3Al-2.5V (ASTM grade 9), Ti-4.5Al-1.5Cr-5Mo (Corona 5), and Ti-0.3Mo-0.8Ni (ASTM grade 12).

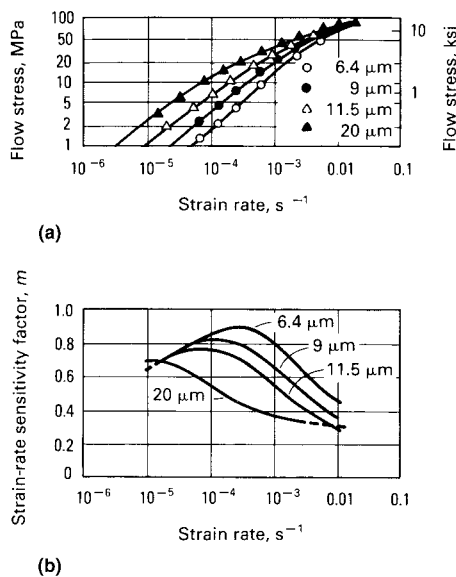

Metallurgical variables that affect superplastic behavior in titanium alloys include grain size, grain size distribution, grain growth kinetics,

diffusivity, phase ratio in  $\alpha$ - $\beta$  alloys, and texture (Ref 1). Alloy composition is also significant, because it has a pronounced effect on  $\alpha$ - $\beta$  phase ratio and on diffusivity.

Grain size is known to have a strong influence on the superplastic behavior of Ti-6Al-4V (Ref 2, 3). This is illustrated in Fig. 1, which shows flow stress and strain-rate sensitivity factor, *m*, as a function of strain rate for Ti-6Al-4V materials with four different grain sizes. Increasing grain size increases the flow stress, reduces maximum *m*-value, and reduces the strain rate at which maximum *m* is observed.

**Grain Size Distribution.** Figure 2 shows flow stress versus strain rate for Ti-6Al-4V alloys with two different grain size ranges. The material with the smaller grain size distribution (lot A) exhibits significantly lower flow stresses than the material with the larger grain size distribution (lot B). Maximum  $m$ -value is also higher for the lot A material.

Grain growth kinetics affect superplastic behavior in direct relation to the grain size developed in the material. A study of grain growth effects on Ti-6Al-4V found that the flow hardening observed during constant strain-rate superplastic flow was the direct result of grain growth (Ref 3). It was also observed that grain growth accelerated with increasing strain rate. This grain growth causes an increase in flow stress and a decrease in maximum  $m$ -value.

**Fig. 1** (a) Flow stress and (b) strain-rate sensitivity factor,  $m$ , versus strain rate for Ti-6Al-4V materials with four different grain sizes. Test temperature: 927 °C (1700 °F). Source: Ref 3

**Fig. 2** Effect of grain size distribution on flow stress versus strain-rate data for Ti-6Al-4V at 927 °C (1700 °F). Lot A, average grain size of 4 μm and grain size range of 1 to 10 μm; lot B, average grain size of 4.6 μm but grain size range of 1 to >20 μm. Source: Ref 4

Diffusivity is an important quantity in the superplastic flow of titanium alloys (and other engineering materials). The best indicator of diffusivity is usually activation energy,  $Q$ , which can be determined from the change in strain rate with temperature (Ref 1). Values of  $Q$  have been determined for several titanium alloys and for the  $\alpha$  and  $\beta$  phases of titanium alloys. As indicated in Table 3, the activation energies determined from superplastic data are consistently higher than those for self-diffusion. It has been suggested that the higher  $Q$  values seen in superplastic alloys are due to the fact that the volume fraction of  $\beta$  phase in the alloys investigated increases with temperature, exaggerating the strain-rate increase and resulting in falsely high  $Q$  values. This complicates efforts to establish specific deformation mechanisms.

**Phase Ratio Effects.** Figure 3 shows that the two-phase ( $\alpha$ - $\beta$ ) titanium alloys seem to exhibit greater superplasticity than other titanium alloys. The  $\alpha$  and  $\beta$  phases are quite different in terms of crystal structure (hexagonal close-packed for  $\alpha$ , and body-centered cubic for  $\beta$ ) and diffusion kinetics. Beta phase exhibits a diffusivity approximately 2 orders of magnitude greater than that of  $\alpha$  phase. For this reason alone it should be expected that the amount of  $\beta$  phase present in a titanium alloy would have an effect on superplastic behavior.

Figure 3 shows elongations and  $m$ -values for several titanium alloys as a function of the volume fraction of  $\beta$  phase present in the alloys. It can be readily seen that elongation values reach a peak at approximately 20 to 30 vol%  $\beta$  phase (Fig. 3a), while  $m$ -values peak at  $\beta$  contents of approximately 40 to 50 vol% (Fig. 3b). Because  $m$  is usually considered to be a good indicator of superplasticity, this discrepancy in the location of maximal of the curves in Fig. 3 may be surprising. It is believed that the difference stems from a grain growth effect during superplastic deformation. Beta phase is known to exhibit more rapid grain coarsening than  $\alpha$ , and the maximum ductility may be the result of a balance between moderated grain growth (due to the presence of  $\alpha$  phase) and enhanced diffusivity (due to the presence of  $\beta$ ).

## General Formability

Titanium metals exhibit a high degree of springback in cold forming. To overcome this characteristic, titanium must be extensively overformed or hot sized after cold forming. Aging or stress-relief operations are usually conducted on titanium alloys that are cold formed. Straightening can be done during the aging or stress-relief cycle with proper tools.

**Table 3** Activation energies for superplastic deformation and self-diffusion in titanium alloys

Alloy	Temperature range		Activation energy ( $Q$ ), kcal/mol	Ref

(b)

**Fig. 3** (a) Elongation and (b)  $m$ -value as a function of  $\beta$ -phase content for several titanium alloys

Hot forming does not greatly affect final properties. Forming at temperatures ranging from 595 to 815 °C (1100 to 1500 °F) allows the material to deform more readily and simultaneously stress relieves the deformed material; it also minimizes springback. The net effect in any forming operation depends on total deformation and actual temperature during forming. Because titanium metals tend to creep at elevated temperature, holding under load at the forming temperature (creep forming) is another alternative for achieving the desired shape without the need to compensate for extensive springback.

**The Bauschinger Effect.** In all forming operations, titanium and its alloys are susceptible to the Bauschinger effect, which is a drop in compressive yield strength subsequent to tensile straining and vice versa. The Bauschinger effect, unlike the strain-hardening behavior observed in other metals, involves stress-strain asymmetry that results in hysteretic stress-strain loops such as those shown schematically in Fig. 4. The Bauschinger effect is most pronounced at room temperature; plastic deformation (1 to 5% tensile elongation) at room temperature always introduces a significant loss in compressive yield strength, regardless of the initial heat treatment or strength of the alloys. At 2% tensile strain, for example, the compressive yield strength of Ti-6Al-4V drops to less than one-half the value for solution-treated material. Increasing the temperature reduces the Bauschinger effect; subsequent full thermal stress relieving completely removes it.

The Bauschinger effect can be removed at temperatures as low as the aging temperature in

solution-treated titanium alloys. Heating or plastic deformation at temperatures above the normal aging temperature for solution-treated Ti-6Al-4V will cause overaging; as a result, all mechanical properties will decrease.

## Sheet Preparation

Before titanium sheet is formed, it should be inspected for flatness, uniformity, and thickness. Some manufacturers test incoming material for hardness, strength, and bending behavior.

Critical regions of titanium sheet should not be nicked, scratched, or marred by tool or grinding marks, because the metal is notch sensitive. All scratches deeper than the finish produced by 180-grit emery should be removed by sanding the surface. Edges of the workpieces should be smooth, and scratches, if any, should be parallel to the edge of the blank to prevent stress concentration that could cause the workpiece to break. To aid in forming, surface oxide or scale should be removed before forming.

**Cleaning.** Grease, oil, stencils, fingerprints, dirt, and all chemicals or residues that contain halogen compounds must be removed from titanium before any heating operation. Salt residues on the surface of the workpiece can cause hot-salt cracking in service or in heat treating; even the salt from a fingerprint can cause problems. Therefore, titanium is often handled with clean cotton gloves after cleaning and before hot forming, hot sizing, or heat treatment.

Ordinary cleaners and solvents such as isopropyl alcohol and acetone are used on titanium. Halogen compounds, such as trichlorethylene, should not be used, unless the titanium is pickled in acid after cleaning.

Titanium that has been straightened or formed with tools made of lead or low-melting alloy should be cleaned in nitric acid. Detailed information on the cleaning of titanium is given in the article "Surface Engineering of Titanium and Titanium Alloys" in *Surface Engineering*, Volume 5 of *ASM Handbook*, 1994.

Grinding the sheet to final thickness leaves marks in titanium that can be moderated in an aqueous acid bath containing (by volume) 30% concentrated nitric acid and not more than 3% hydrofluoric acid. Failure to keep the ratio of nitric to hydrofluoric acid at 10 to 1 or greater (to suppress the formation of hydrogen gas during pickling), or the use of any pickling bath that produces hydrogen, can result in excessive hydrogen pickup. The acid bath should remove 0.025 to 0.075 mm (0.001 to 0.003 in.) of thickness from each surface to eliminate the marks made by abrasives. Titanium should be washed or cleaned before it is immersed in acid. The material left on the surface may protect the surface from the acid.

After thermal exposure, thin oxides that form at temperatures below 540 °C (1000 °F) can be removed by acid pickling. Very tenacious oxides may require grit blasting prior to pickling.

Exposure above 540 °C (1000 °F) forms an oxygen-rich surface layer on titanium. This surface is made up of a scale and an alpha case layer. The scale is normally reduced by the use of scale-inhibiting coatings put on prior to the thermal exposure. Scale can also be removed by abrasive blasting; however, this may cause distortion in thin parts. The removal of this scale prior to metal removal in the cleaning process improves the surface appearance. The alpha case layer is a brittle layer that must be removed to restore the base metal properties. Chemical milling, machining, or other similar methods accomplish the surface removal. Another method of limiting the formation of the oxygen-rich surface layer is to use a protective atmosphere or vacuum. Argon gas is a commonly used atmosphere for superplastic forming. Argon is applied to one side, with the other being exposed to air. This can cause an alpha case thickness difference from one side to the other.

## Trimming

Blanking of titanium alloy sheet and plate 6.4 mm (0.25 in.) thick or less is done in a punch press. As with other metals, maximum blank size depends on stock thickness, shear strength, and available press capacity. Dies must be rigid and sharp to prevent cracking of the work metal. Hardened tool steel must be used for adequate die life.

In one application, holes 6.4 mm (0.25 in.) in diameter were punched in 1.02 to 3.56 mm (0.040 to 0.140 in.) thick annealed alloy Ti-6Al-4V sheet to within  $\pm 0.051$  mm ( $\pm 0.002$  in.) of diameter and with surface roughness of less than 1.3 mm (0.05 in.). The best holes were produced with flat-point punches having 0.025 mm (0.001 in.) die clearance.

Shearing of titanium sheet up to 3.56 mm (0.140 in.) thick can generally be done without difficulty; with extra care, titanium sheet as thick as 6.0 mm (0.25 in.) can be sheared. Shears intended for low-carbon steel may not have enough holddown force to prevent titanium sheets from slipping. A sharp shear blade in good condition with a capacity for cutting 4.8 mm (0.188 in.) thick low-carbon steel can cut 3.2 mm (0.125 in.) thick titanium sheet. Cutters should be kept sharp to prevent edge cracking of the blank.

Sheared edges, especially on thicker sheet metal, can have straightness deviations of 0.25 to 5 mm (0.01 to 0.20 in.), usually because the shear blade is not stiff enough. Shearing can cause cracks at the edges of some titanium sheet thicker than 2.0 mm (0.080 in.). If cracks or other irregularities develop in a critical portion of the workpiece, an alternative method of cutting should be used, such as band sawing, abrasive waterjet cutting, or laser cutting (see the articles "Abrasive Waterjet Cutting" and "Laser Cutting" in this Volume).

Slitting of titanium alloy sheet can be done with conventional slitting equipment and with

**Fig. 4** Schematics showing two types of hysteresis stress-strain loops resulting from the Bauschinger effect in titanium alloys. Source: Ref 12

draw-bench equipment. Slitting shears are capable of straight cuts only; rotary shears can cut gentle contours (minimum radii: ~250 mm, or 10 in.). The process can be used for sheet thickness to 2.54 mm (0.100 in.).

Band sawing prevents cracking at the edges of titanium sheet but causes large burrs. This is usually followed by an edge-sanding operation to remove burrs.

Nibbling can be used to cut irregular blanks of titanium, but most blanks need filing or sanding after nibbling to produce a uniform edge.

All visual evidence of a sheared or broken edge on a part should be removed by machining, sanding, or filing before final deburring or polishing. All rough projections, scratches, and nicks must be removed. Extra material must be allowed at the edges of titanium blanks so that shear cracks and other defects can be removed. On sheared parts, a minimum of 0.25 mm (0.010 in.) must be removed from the edge; on punched holes, 0.35 mm (0.014 in.). On parts cut by friction band sawing or abrasive sawing, 6.35 mm (0.25 in.) or one thickness of sheet should be removed, whichever is the smaller.

The lay of the finish on the edges of sheet metal parts should be parallel to the edge surface of the blank, and sharp edges should be removed. Edges of shrink flanges and stretch flanges must be polished before forming. To prevent scratching the forming dies, edges of holes and cutouts should be deburred on both sides and should be polished where they are likely to stretch during forming.

## Tool Materials and Lubricants

**Tool materials** for forming titanium are chosen to suit the forming operation, forming temperature, and expected quantity of production. The cost of tool material is generally a small fraction of the cost of tools, unless forming temperature is such that heat-resistant alloy tooling is required. Cold forming can be done with epoxy-faced aluminum, steel, or zinc tools. Hot forming tools are fabricated from ceramic, cast iron, tool steel, stainless steel, and nickel-base alloys. Materials selection is based on the service temperature, hardness of the material and tool at the forming temperature, and the number of parts being formed. Tool steel does not work well when temperatures are above the tempering temperature of the steel or above the temperatures where oxides form on the tool.

Titanium alloys are often formed in heated dies and presses that have a slow, controlled motion and that can dwell in the position needed during the press cycle. Hot forming is sometimes done in dies that include heating elements or in dies that are heated by the press platens. Press platens heated to 650 °C (1200 °F) can transmit enough heat to keep the working faces of the die at 425 to 480 °C (800 to 900 °F). Other methods of heating include electrical-resistance heating and the use of quartz lamps and portable furnaces.

Tool materials for the superplastic forming of titanium alloys are a special case (see the section "Superplastic Forming" in this article). They must be able to withstand the high temperatures (870 to 925 °C, or 1600 to 1700 °F) required for superplastic forming. Cast ceramics, 22-4-9 stainless steel (Fe-0.5C-22Cr-9Mn-4Ni), and 49M steel are used for this purpose. Figure 5 shows a typical tool used at elevated temperatures, in the 870 to 925 °C (1600 to 1700 °F) range. The heavy scale and oxide layer is due to the long exposure at elevated temperatures. Dies are usually cleaned between production runs to keep the surface smooth and ensure an acceptable finish on the parts.

**Lubricants.** Galling is the most severe problem to be overcome in hot forming. Lubricants may react unfavorably with titanium when it is heated, although molybdenum disulfide suspended in a volatile carrier, colloidal graphite, and graphite-molybdenum disulfide mixtures have been successfully used. Boron nitride slurries also are used. If the lubricant reacts with oxidation products to produce a tenacious surface coating, it must be removed by sandblasting with garnet grit or 120-mesh aluminum oxide, followed by acid pickling. Parts can be preformed cold and hot sized to minimize the

galling effects seen in hot forming parts; however, this is not always practical.

Boron nitride is the preferred temperature-resistant lubricant because of its higher lubricity, as well as ease of application and removal. Other lubricants used for hot forming have a graphite, molybdenum disulfide, or  $Y_2O_3$  base.

Lubricants for the cold forming of titanium are generally similar to those used for the severe forming of aluminum alloys (see the articles "Forming of Aluminum Alloys" and "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume). Tool materials and lubricants for the cold and hot forming of titanium alloys are given in Table 4.

## Cold Forming

Commercially pure titanium and the most ductile metastable  $\beta$  titanium alloys, such as Ti-15V-3Sn-3Cr-3Al and Ti-3Al-8V-6Cr-4Zr-4Mo, can be formed cold to a limited extent. Alloy Ti-8Al-1Mo-1V sheet can be cold formed to shallow shapes by standard methods, but the bends must be of larger radii than in hot forming and must have shallower stretch flanges. The cold forming of other alloys generally results in

**Fig. 5** Typical tool finish after being exposed to elevated temperatures. This hot forming die has a heavy scale and oxide layer caused by long exposure to high temperatures. Dies must be cleaned using abrasives in between production runs in order to avoid mark-off being transferred to the part surface. The light area is alpha case that has been migrated to the die from the titanium parts.

excessive springback, requires stress relieving between operations, and requires more power.

Titanium and titanium alloys are commonly stretch formed without being heated, although the die is sometimes warmed to 150 °C (300 °F). For the cold forming of all titanium alloys, formability is best at low forming speeds.

Hot sizing and stress relieving are ordinarily needed to improve part contour, reduce stress, and avoid delayed cracking and stress corrosion. Stress relief is also needed to restore compressive yield strength after cold forming. Hot sizing is often combined with stress relieving, by holding the workpiece in fixtures or form dies to prevent distortion. Stress-relief treatments for CP titanium and some titanium alloys are given

in Table 5. Hot sizing for shorter times than reflected in the table will remove the springback on some materials. This would indicate that shorter times may be acceptable. Detailed information on the heat treatment of titanium alloys is available in the article "Heat Treating of Titanium and Titanium Alloys" in *Heat Treating*, Volume 4 of *ASM Handbook*, 1991.

The only true cold-formable titanium alloy is Ti-15V-3Sn-3Cr-3Al. Hot sizing is usually not used for this alloy; however, properties must be developed with an aging treatment (8 h at 540 °C, or 1000 °F, is typical). Because of the high springback rates encountered with this alloy, more elaborate tooling must be used. Hot sizing can be used at the solution-treatment

temperature, followed by air cooling. This helps to solve the springback problems seen during the aging process. A restraint fixture can also be used to straighten during aging.

## Hot Forming

Heating titanium increases formability, reduces springback, takes advantage of a lesser variation in yield strength, and allows for maximum deformation with minimum annealing between forming operations. Severe forming must be done in hot dies, generally with preheated stock. Figure 6 shows the removal of a set of curved channels after being hot formed from a flat sheet. The flat sheet is located in the die and allowed to heat up to temperature. Pressure is slowly applied, bringing down the matching punch and holding for 10 min under pressure prior to removal. Hot forming is ordinarily done at 730 °C (1350 °F) for Ti-6Al-4V material.

The greatest improvement in the ductility and uniformity of properties for most titanium alloys is at temperatures above 540 °C (1000 °F). At still higher temperatures, some alloys exhibit superplasticity (see the section "Superplastic Forming" in this article). However, contamination is also more severe at the higher temperatures. Above approximately 870 °C (1600 °F), forming should be done in vacuum or under a protective atmosphere, such as argon, to minimize oxidation. When done in air, metal removal is required to remove the oxygen-rich layer that forms on the surface of the titanium.

As indicated in Table 6, most hot forming operations are done at temperatures above 540 °C (1000 °F). For applications in which the utmost in ductility is required, temperatures below 315 to 425 °C (600 to 800 °F) are usually avoided. Alpha-beta alloys should not be formed above the  $\beta$ -transus temperature.

Temperatures generally must be kept below 815 °C (1500 °F) to avoid marked deterioration in mechanical properties. Superplastic forming, however, is performed at 870 to 925 °C (1600 to 1700 °F) for some alloys, such as Ti-6Al-4V. At these temperatures, care must be taken not to exceed the  $\beta$ -transus temperature of Ti-6Al-4V. Heating temperature and time at temperature must be controlled so that the titanium is hot for the shortest time practical and the metal temperature is in the correct range.

Reference 14 gives details about forming and the tolerance that can be expected, as well as some of the strength effects. The equipment used is described in detail. The information was generated in 1968 and reflects much of the technology of the day. Some of the forming tools have been improved, and some have not changed.

Hot sizing is used to correct inaccuracies in shape and dimensions in preformed parts. Hot forming takes a flat blank and forms it to the final shape. Hot sizing uses the creep-forming principle to force irregularly shaped parts to assume

**Table 4 Tool materials and lubricants used for forming titanium alloys**

Operation(s)	Tool materials	Lubricants
<b>Cold forming</b>		
Press forming, drawing, drop hammer forming	Cast zinc die or lead punch with stainless steel caps	Graphite suspension in a suitable solvent
Press-brake forming	4340 steel (36–40 HRC)	Graphite suspension in a suitable solvent
Contour roll forming, three-roll forming	AISI A2 tool steel	SAE 60 oil
Stretch forming	Epoxy-faced cast aluminum, cast zinc, cast bronze	Grease-oil mixtures, wax; 10:1 wax-graphite mixture
<b>Hot forming</b>		
Press forming, drawing, drop hammer forming	High-silicon cast iron, stainless steels, heat-resistant alloys	Graphite suspension, boron nitride
Sizing	Low-carbon steel, high-silicon gray or ductile iron, AISI H13 tool steel, stainless steels, heat-resistant alloys	Graphite suspension, boron nitride
Press-brake forming	AISI H11 or H13 tool steel, heat-resistant alloys	Graphite suspension, boron nitride
Contour roll forming, three-roll forming	AISI H11 or H13 tool steel	Graphite suspension, boron nitride
Stretch forming	Cast ceramics, AISI H11 or H13 tool steel, high-silicon gray iron	Graphite suspension, 10:1 wax-graphite mixture, boron nitride
Superplastic forming	Ceramics, 22-4-9 stainless steel, 49M heat-resistant steel	Boron nitride

**Table 5 Stress-relief schedule for titanium and titanium alloys**

Alloy	Stress-relief temperature		Time, min
	°C	°F

the correct shape against a heated die by the controlled application of horizontal and vertical forces over a period of time. Some buckles and wrinkles can be removed from preformed parts in this way. A combination of creep and compression forming is used when reducing bend radii by hot sizing. The effect of temperature on the properties of the metal may limit the maximum useful temperature. Figure 7 shows the setup for creep forming a B-737 part using a hot ceramic die in a conventional furnace. The die is heated up in the furnace, then rolled out and separated. The blank is placed in the tool, the die is then closed up, and weight is added to the top. The tool and weights are then rolled back into the furnace and held at temperature for a period of time sufficient to allow for the creep forming of the part to contour, prior to rolling the tool out,

removing the formed part, and placing another blank into the tool.

Hot platen presses are commonly used for the hot sizing and forming of titanium. The tooling is designed for holding the workpiece to the required shape for the necessary time at temperature. Hot forming/sizing in hot platen presses is done in the following sequence of operations:

- Parts are usually cleaned and coated with a scale inhibitor.
- Parts are loaded on hot forming tools, the press closed, and the parts allowed to heat up prior to applying the forming force.
- Force is applied through the platens and auxiliary side rams as required and held to complete the forming/annealing cycle.

- Parts are removed and cooled in a uniform manner. Hot parts are very susceptible to handling distortion.

Some hot forming temperatures are high enough to age a titanium alloy. Heat-treatable  $\alpha$ - $\beta$  alloys generally must be resolution heat treated after hot forming. Some of the metastable  $\beta$  alloys have solution temperatures in the hot forming range and can be resolution heat treated during the hot forming operation. Solution heat treating thin-gage alloys that require water quench is risky because of distortion.

Hot forming has the advantage of improved uniformity in yield strength, especially when the forming or sizing temperature is above 540 °C (1000 °F). However, care must be taken to limit the accumulation of dimensional errors resulting from:

- Differences in thermal expansion
- Variations in temperature
- Dimensional changes from scale formation
- Changes in dimensions of tools
- Reduction in thickness from chemical pickling operations

## Superplastic Forming

The superplastic forming of titanium is currently being used to fabricate a number of sheet metal components for a range of aircraft and aerospace systems. Hundreds of parts are in production, and significant cost savings are being realized through the use of superplastic forming. Additional advantages of superplastic forming over other forming processes include the following:

- Very complex part configurations are readily formed.
- Lighter, more efficient structures are possible.
- It is performed in a single operation, reducing fabrication labor time.
- Depending on part size, more than one piece can be produced per machine cycle.
- The force needed for forming is supplied by a gas, resulting in the application of equal amounts of pressure to all areas of the workpiece.

Superplastic forming is similar to vacuum forming of plastics. A computer system is used to control the gas pressure so that the part forms into the cavity at a constant strain rate. The Ti-6Al-4V material is generally used for this process; however, there are other alloys that work. The material needs to have fine, equiaxed grains and high elongation at the elevated temperature.

The superplastic forming process puts the part on top of a cavity die, as shown in Fig. 8(a). With the tool and blank heated up to forming temperatures in the superplastic range, gas pressure is applied at a predetermined rate to keep a constant strain rate. As the part is formed down into smaller features, the pressure is increased to maintain the strain rate, and the thickness

decreases. The resultant process produces a part that has thinned out based on the geometry of the die (Fig. 8b). There are variations to this process to improve thickness distributions in die design and how the parts are formed.

Figure 9 shows a part blank being loaded onto a hot die in a shuttle press. The lower platen shuttles out on a track to make loading and unloading much easier. The operators wear reflective suits to protect them from the thermal exposure. The tool only needs to reflect one side of the part, whereas, in hot sizing the tool matches both sides of the part.

The limitations of the process include:

- Heat-resistant tool materials are required.
- Equipment that can provide high temperatures and tonnage to balance forming pressures is necessary.
- Long preheat times are necessary to reach the forming temperature.
- A protective atmosphere, such as argon, is helpful.

Several forming processes are used in the superplastic forming of titanium alloys. Among these are blow forming, vacuum forming, thermoforming, deep drawing, and superplastic forming/diffusion bonding (see the section “Superplastic Forming/Diffusion Bonding” in this article). All of these processes are discussed in more detail in the article “Superplastic Sheet Forming” in this Volume.

## Superplastic Forming/Diffusion Bonding

The superplastic forming process can be enhanced with diffusion bonding (solid-state joining). Both processes require similar conditions, such as heat, pressure, clean surfaces, and an inert environment. The combined process is referred to as superplastic forming/diffusion bonding (SPF/DB). Diffusion bonding can be carried out as the first part of the superplastic forming cycle, thus eliminating the need for welding or brazing for complex parts.

The SPF/DB process has greatly extended the applicability of superplastic forming. Using SPF/DB, a sheet can be diffusion bonded and formed onto preplaced details, or two or more sheets can be bonded and formed at selected locations. Figure 10 illustrates the SPF/DB process for three-sheet parts.

Diffusion bonding can be applied only to selected areas of a part by using a stop-off material (Fig. 10 step 1, and Fig. 11) that is placed between the sheets at locations where no bonding is desired. Suitable stop-off materials depend on the alloy being bonded and the temperatures employed; yttria and boron nitride have been successfully used. The powder is mixed and applied to the part in selected areas using the silk screening process (Fig. 11). Figure 10, step 2 shows the sheets sealed into an airtight pack. In step 3, the pack is bonded

**Fig. 7** Creep forming a part for the B-737 in a ceramic die using a conventional furnace. The titanium is pushed into the correct shape through the application of heat, weight, and time.

**Fig. 8** Superplastic forming of titanium. (a) Setup at the start of the forming cycle. (b) After forming is completed

**Fig. 9** Loading a sheet of titanium into a superplastic forming die

together under pressure and temperature. In step 4, the pack is inflated to start forming areas where the stop-off material was applied. Step 5 completes the forming cycle, fully forming the part prior to removal.

Diffusion bonding in combination with superplastic forming can produce lightweight panel structures, as shown in Fig. 12.

Superplastic forming and SPF/DB are gaining acceptance in the aircraft/aerospace industry. Figure 13 shows the increase in applications for superplastically formed titanium parts in four military aircraft since 1980; applications for commercial aircraft and in the aerospace industry also are increasing. Inspection of the bond is usually done with ultrasonic inspection methods.

Fig. 10 Schematic showing the sequence of operations for superplastic forming/diffusion bonding of three-sheet titanium parts

Fig. 12 Typical lightweight panels produced with diffusion bonding and superplastic forming

Mechanical analysis of the joint and bond is based on part configuration.

Applications range from simple clips and brackets to airframe components and other load-bearing structures. Figures 14 and 15 show current applications for superplastically formed parts and illustrate the cost and weight savings that can be realized by using superplastic forming. Reducing the part count and assembly costs and making a more structurally efficient part result in cost and weight savings.

## Press-Brake Forming

Titanium alloys cold formed in a press brake behave like work-hardened stainless steel, except that springback is considerably greater (see the article "Forming of Stainless Steel" in this Volume). If bend radii are large enough, forming can be done cold. However, if bend radii are small enough to cause cracking in cold forming, either hot forming or the process of cold forming followed by hot sizing must be used.

The setup and tooling for press-brake air bending are relatively simple because the ram stroke determines the bend angle. The only tooling adjustments are the span width of the die and the radii of the punch. The span width of the

Fig. 11 Typical silk screen application of the stop-off material

die affects the formability of bend specimens and is determined by the punch radius and the work metal thickness, as shown in Fig. 16. Acceptable conditions for dies in press-brake forming are shown as the shaded area between the upper and lower limits in Fig. 16.

The minimum bend radius obtainable in press-brake forming depends on the alloy, work metal thickness, and forming temperature (Table 7). Springback in press-brake forming depends on the ratio of punch radius (bend radius) to stock thickness and on forming temperature, as shown in Fig. 17 for alloy Ti-6Al-4V (Fig. 17 is not to be used for minimum bend radii).

Hot-brake forming puts linear bends in a sheet by heating up the blank, then forming in a cold press brake. When this technique is used, a stress relief follows because the forming takes place quicker than the stress-relief time required to prevent springback of the part. Springback appears to be approximately the same with the blank heated as with a cold blank when the forming takes place very quickly. This process appears to work well when the bend radii is three times the thickness or larger in Ti-6Al-4V material. It is difficult to determine the temperature at which the forming takes place.

The deep drawing of titanium alloys is limited to the more formable alloys, such as CP titanium in the lower-strength grades. Superplastic forming can also be used for deep drawing; however, a draft angle is usually required because it is difficult to remove parts from a shape that has vertical sides, unless there is a guided removal system that keeps the part aligned.

However, general guidelines for the deep drawing of titanium alloy into dome shapes at room temperature are:

- The edges and surface of the blank should be smooth to prevent cracking during forming.
- The flange radius should be at least 9.5 to 12.7 mm (0.375 to 0.500 in.).
- The workpiece should be clean before each forming operation.
- An overlay or pressure cap can be used to prevent wrinkles.

(b)

**Fig. 15** Ti-6Al-4V engine nacelle component for the Boeing 757 aircraft. (a) Part as previously fabricated required 41 detail parts and more than 200 fasteners. (b) Superplastically formed part is formed from a single sheet.

- Severe forming and localized deformation should be avoided; forming pressure should be applied slowly.
- The punch should be polished to prevent galling, regardless of lubrication. Often, it is preferred to weld a layer of hard bronze on top of more conventional tooling steels to minimize galling and damage to the part, the tool, or both.

The deep drawing of dome and hemisphere shapes has also been accomplished at room temperature in a rubber-diaphragm press. A detailed description of rubber-diaphragm forming is available in the article "Rubber-Pad Forming and Hydroforming" in this Volume. Deep drawing is discussed in more detail in the article "Deep Drawing" in this Volume.

**Hot Drawing.** At temperatures of approximately 675 °C (1250 °F), titanium can be drawn deeper, with more difficult forming than at room temperature. Generally, depth of draw depends on material, workpiece shape, required radii, forming temperature, die design, die material, and lubricant. The setup becomes more critical than in hot sizing because the sides become more vertical. A setup that resembles a cold forming die works best to maintain alignment of the tools, and the tool is only heated where it contacts the part. Normal hot sizing presses usually have distorted heated platens that make alignment difficult when making vertical draws.

## Power (Shear) Spinning

Most titanium alloys are difficult to form by power spinning. Alloys Ti-6Al-4V and some grades of CP titanium are the most responsive to forming by this method.

Most tools for the power spinning of titanium are made of high-speed steel and hardened to 60 HRC. Mandrels are heated for hot spinning, though. It may be advantageous to heat the workpiece also. Tube preforms can be heated by radiation. The hot power spinning of titanium is done at 205 to 980 °C (400 to 1800 °F), depending on the alloy and the operation.

**Fig. 16** Optimal relationships among span width of die, punch radius, and work metal thickness in the press-brake forming of titanium alloys. Shaded area indicates acceptable forming limits.

**Lubricants** for the power spinning of titanium depend on the forming temperature used. At temperatures up to 205 °C (400 °F), heavy drawing oils, graphite-containing greases, and colloidal graphite are used. Colloidal graphite and molybdenum disulfide are employed at temperatures to 425 °C (800 °F); above this temperature, colloidal graphite, powdered mica, and boron nitride are used. More information on power spinning is available in the article "Spinning" in this Volume.

## Rubber-Pad Forming

The cold forming of titanium in a press with tooling that includes a rubber pad is used mostly for flanging thin stock and for forming beads and shallow recesses. The capacity of the press controls the range in size, strength, and thickness of blanks that can be formed. Within this range, however, additional limits may be set by buckling and splitting. Auxiliary devices, such as overlays, wiper rings, and sandwiches, are usually needed in rubber-pad forming to improve the forming and to reduce the amount of wrinkling and buckling. Rubber-pad forming is generally done at room temperature or with only moderate heat. Forming is almost always followed by hot sizing to remove springback, to sharpen radii, to smooth out wrinkles and

buckles, to stress relieve, and to complete the forming. Handwork is sometimes needed to complete the forming.

Sharp bends can be made at higher forming pressures. Figure 18 shows the effect of pad pressure on bend radius for two titanium alloys.

Springback behavior of titanium and its alloys in rubber-pad forming differs somewhat from that observed in other methods of forming. In general, springback in forming titanium varies directly with the ratio of bend radius to work metal thickness, and inversely with forming temperature. Springback is also inversely proportional to forming pressure.

Beads can be formed to a limited extent in titanium alloy sheet by rubber-pad forming. However, beads are readily formed by superplastic forming, and this process is preferred. Additional information on rubber-pad forming is available in the article "Rubber-Pad Forming and Hydroforming" in this Volume.

## Stretch Forming

Tooling that is used for the stretch forming of stainless steel is generally suitable for the cold stretch forming of titanium, when used with a high clamping force that will prevent slipping and tearing. Particular attention should be paid to the tooth or serration pattern for the jaws to preclude slipping and/or breaking. Titanium may exhibit irregular incremental stretch under tension loads; therefore, optimal results are obtained when titanium is stretch formed at slow strain

rates. The rate of wrapping around a die should be no more than 205 mm/min (8 in./min). Post-stretching of Ti-6Al-4V material does not work well because it is very notch sensitive and may break. Lower-strength CP titanium stretch forms well. In general, material preparation is critical for cold stretching of titanium alloys due to the notch sensitivity.

In the stretch forming of angles, channels, and hat-shaped sections, deformation occurs mainly by bending at the fulcrum point of the die surface; compression buckling is avoided by applying enough tensile load to produce approximately 1% elongation in the inner fibers. The outer fibers elongate more; the extent depends on the curvature of the die and on the shape of the workpiece. It is sometimes preferable or required (especially if sufficient forming power is not available) to stretch wrap at elevated temperature. Again, the wrapping speed must be slow to prevent local overheating or necking.

Formability limits can be extended by permitting small compression buckles to occur at the inner fibers and removing them later by hot sizing. The buckled region represents a condition of overforming and should be limited to the amount that can be effectively removed by hot sizing. Care must be taken to only permit buckling that can be removed. Small, sharp wrinkles may indent the hot sizing tool rather than be removed.

Compression buckling is not a problem when sheet is stretch formed to produce single or compound curves. The ductility of sheet varies with orientation and is generally better when the direction of rolling concedes with the direction of stretching. In the stretch forming of compound curves, the stretching force should be applied in the direction of the smaller radius. The rate of wrapping around the die should be no more than 205 mm/min (8 in./min).

Stretch forming is being replaced in many applications by superplastic forming. Additional information on the stretch forming process is available in the article "Stretch Forming" in this Volume.

**Fig. 18** Effect of pad pressure on radii formed in 1.60 mm (0.063 in.) thick titanium alloy sheets at room temperature

## Contour Roll Forming

Titanium sheet can be contour roll formed like any other sheet metal, but with special consideration for allowable bend radius and for the greater springback that is characteristic of titanium. Springback is affected to some extent by roll pressure. Often, hot rolling must be done on heated work metal with heated rolls. Additional information is available in the article "Contour Roll Forming" in this Volume.

Roll forming is an economical method of forming titanium alloy sheet into aircraft skins, cylinders, or parts of cylinders. The sheet should be flat within 0.15 mm (0.006 in.) for each 51 mm (2 in.) of length. The corners of the sheet should be chamfered to prevent marking of the rolls.

The upper roll of the three-roll assembly can be adjusted vertically. The radius of the bend is controlled by the roll adjustment. Premature failure will occur if the contour radius is decreased too rapidly; however, too many passes through the rolls may cause excessive work hardening of the work metal. Several trial parts must sometimes be made in a new material or shape to establish suitable operating conditions.

Three-roll forming is also used to form curves in channels that have flanges of 38 mm (1.5 in.) or less. Figure 19 shows the use of the process for curving a channel with the heel in. Transverse buckling and wrinkling are common failures in the forming of channels. The article "Three-Roll Forming" in this Volume contains more information on this process.

## Creep Forming

In creep forming, heat and pressure are combined to cause the slow forming of titanium sheet into various shapes, such as double-curve panels, channel sections, Z-sections, large rings, and small joggles. The metal flows plastically at a stress below its yield strength. At low temperature, creep rates are ordinarily very low (for example, 0.1% elongation in 1000 h), but the creep rate of titanium accelerates sharply with increasing temperature.

Creep forming/hot straightening is done by applying a force on the part over a period of time while the part is at temperature. The desired effect is to force the part into the correct configuration while stress relieving. This will ensure that the part stays in the correct configuration when cooled down. Methods may include the following:

- A blank is clamped at the edges, as for stretch forming, and a heated male tool is loaded to press against the unsupported portion of the blank; the metal yields under the combination of heat and pressure and slowly creeps to fit the tool.
- The part is located on a tool with weights and run through a stress-relief cycle. During this cycle, the part will deform into the correct configuration.
- The part is forced into the correct configuration, then a stress-relief cycle is run.

**Fig. 19** Use of three-roll forming to produce a curve in a U-section channel

- A heated die and vacuum bag is used. The blank is placed in the tool under heat and a vacuum is applied to produce the necessary forming force, then the part is run through a stress-relief cycle. Additional time and/or pressure may be required to obtain the desired contour.

Temperatures for creep forming are the same as those used in hot forming (Table 6). Generally, titanium must be held at the creep-forming temperature for 3 to 20 min per operation; creep forming sometimes takes as long as 2 h.

## Vacuum Forming

Large panels (some as much as 18 m, or 60 ft, long) for aircraft are sometimes vacuum formed from titanium alloy sheet. Vacuum forming, however, can be by superplastic forming for smaller panels. There are some advantages to developing stand-alone vacuum forming tools, because they tend to be simpler to maintain and do not require a large press to create the forces. For vacuum forming, the blank is laid on a die of heated concrete, ceramic, or metal, and a somewhat larger flexible diaphragm is laid on top of the blank to provide a seal around its edges. Usually, insulation is placed between the part and the flexible diaphragm. This helps to hold in the heat as well as keep the heat off the diaphragm. It should be noted that the water needs to be removed from concrete and ceramic material through a proper curing cycle prior to heating, or it will come out in a most unsatisfactory way. Ceramic material is normally preferred because it has a very low coefficient of expansion and does not flake off under a temperature gradient. After the blank has been heated to forming

temperature, the air is pumped out from between the blank and the die so that atmospheric pressure is used to form the work. This method, a kind of creep forming, cannot bend the work to sharp radii. Finite element analysis, similar to that done for superplastic forming, can be used to determine forming capabilities at a given pressure, temperature, and time.

## Drop Hammer Forming

Forming of titanium using drop hammers is becoming a lost art and perhaps the method of last resort. The tooling is quick, and the method does provide a preform. Hot sizing is required to obtain the desired contour. As shown in Fig. 20, a heat source is normally used to preheat the blank prior to forming. The alloys used in hammer tools contain lead, zinc, and other low-melting metals that contaminate titanium. These need to be removed from the titanium prior to heating. This can be done in a couple of ways. One is to not permit lead, zinc, or other low-melting metals that contaminate titanium to come in contact with the titanium. To do this, the drop hammer tools can be capped with sheet steel, stainless steel, or nickel alloy, depending on the expected tool life. Nickel-base alloys, in thicknesses of 0.635 to 0.813 mm (0.025 to 0.032 in.), have the longest life. The other way is to chemically remove the contamination from the titanium prior to reheating.

As indicated in Table 6, severe forming of most titanium alloys, which includes drop hammer forming, is done at approximately 500 to 800 °C (900 to 1500 °F). Thermal expansion of the dies must be considered in the design. The approximate rate of expansion for steel dies is 0.006 mm/mm (0.006 in./in.). The expansion

**Fig. 20** Drop hammer forming showing oven next to the drop hammer

rate will be different for different alloys and temperatures.

Multistage tools can be used if the part shape is complex and cannot be formed in one blow. The minimum thickness of titanium sheet for drop hammer forming is 0.635 mm (0.025 in.); thicker sheet is used for complex shapes. Minimum thickness is determined from a number of variables. Contour will cause buckling in the thinner gages. Surface damage seems to occur more on the thinner gages. Total tolerance on parts formed in drop hammers is usually 1.6 mm (0.06 in.). Typically, hammer forming is used as a preform to hot sizing. More information on the drop hammer forming process is available in the article "Drop Hammer Forming" in this Volume.

## Joggling

Joggling is frequently done on titanium alloy sheet. A joggle is an offset in a flat plane, consisting of two parallel bends in opposite directions at the same angle (Fig. 21). Generally, the joggle angle is less than 45°.

Depending on joggle depth, joggles can be either formed completely at room temperature or at elevated temperature in press brakes and mechanical or hydraulic presses. Room-temperature joggle limits are given in Table 8. The practice is to preform at room temperature and then hot size ("set" the joggle) in a heated die. The sizing operation is usually done under conditions that result in stress relieving or aging.

Joggles with radii smaller than the minimum bend radii (Table 7) at room temperature, or joggles with length-to-depth ratios of less than approximately 6 to 1, are more successfully formed at elevated temperature. Forming temperature varies between 315 and 650 °C (600 and 1200 °F), depending on the alloy and its heat treated condition. Annealed alloys are joggled at 315 to 425 °C (600 to 800 °F). Heat treated or partly heat treated alloys are joggled at, or near, their aging temperature.

## Dimpling

Dimpling produces a small conical flange around a hole in sheet metal parts that are to be assembled with flush or flathead fasteners. Dimpling is most commonly applied to sheets that are too thin for countersinking. Sheets are

**Fig. 21** Details of a joggle. See Table 8 for room-temperature joggle limits of several titanium alloys. *t*, sheet thickness; *D*, joggle height; *L*, joggle length; *A*, joggle allowance. Source: Ref 18

always dimpled in the condition in which they are to be used, because subsequent heat treatment may cause distortion of the holes or dimensional changes in the sheet.

The hot ram-coin dimpling process is generally used. In hot ram-coin dimpling, force in excess of that required for forming is applied to coin the dimpled area and to reduce the amount of springback.

Titanium is dimpled at up to 650 °C (1200 °F) with tool steel dies. If higher temperatures are required, heat-resistant alloy or ceramic tooling is needed in order to prevent deformation of the dies during dimpling. The work metal is usually heated by conduction from the dimpling tools, which are automated to complete the dimpling stroke at a predetermined temperature.

Pilot holes must be drilled, rather than punched, and must be smooth, round, cylindrical, and free of burrs. Because of the notch sensitivity of titanium, care must be taken in deburring the holes.

The amount of stretch required to form a dimple varies with the head and body diameters of the fastener and the bend angle. If the metal is not ductile enough to withstand forming to the

required shape, cracks will occur radially in the edge of the stretch flange, or circumferentially at the bend radius. Circumferential cracks are more common in thin sheet; radial cracks are more common in thick stock.

## Explosive Forming

Within the limits set by its mechanical properties, titanium can be explosive formed like other metals. Explosive forming is most commonly used for cladding titanium to other metals. Titanium is explosive formed using techniques similar to those used for other metals and alloys (see the article "High-Velocity Metal Forming" in this Volume).

## Bending of Tubing

Round tubing of CP titanium and alloy Ti-3Al-2.5V can be formed at room temperature in ordinary draw bending machines. When hot bending is required, the equipment is modified

**Table 8 Room-temperature joggle limits for several annealed titanium alloys**

See Fig. 21 for definitions of joggle dimensions given here, and Table 7 for minimum bend radii.

(a) Maximum bend angles are based on the use of a clamp section three times as long as the diameter of the tubing and on maximum mandrel-ball support of the tubing.

by adding heat to the tools. Minimum and preferred conditions for bending tubing of CP titanium at room temperature and at elevated temperatures are given in Table 9. As indicated in the table, tubing up to 63.5 mm (2.5 in.) in diameter ordinarily is bent at room temperature, while larger sizes are bent at temperatures of 175 to 205 °C (350 to 400 °F). In either case, bend radius is limited chiefly by tubing diameter, but maximum bend angle is affected by both diameter and wall thickness.

Commercially pure titanium deforms locally if tension is not applied evenly. Bending should be slow; rates of  $1/4^\circ$  to  $4^\circ$  per minute are suitable. A lubricant should be used.

Tools used in bending titanium and titanium alloy tubing are shown in Fig. 22. In this type of apparatus, the tubing is gripped between the clamp and the straight portion of the rotating form block tightly enough to prevent axial slip-

**Fig. 22** Tools used for bending titanium tubing. The cleats on the clamp and plug are used only for bending of large-diameter tubing with thin walls. For hot bending, the pressure die and mandrel are integrally heated.

ping during bending. The clamped end of the tubing is supported by a plug. The cleat insert in the clamp and that attached to the end of the plug (Fig. 22) are used only in bending the larger sizes of tubing that have thin walls, for which greater gripping power is needed.

Computers are also being applied to titanium tube bending, especially at large aircraft and aerospace companies. Computer measurement systems are used during bending, and software packages are available that can design bend geometries. Completely automated precision bending can be performed using computers and numerically controlled bending equipment. More information on automated tube bending is available in the article "Bending and Forming of Tubing" in this Volume.

Drawing oils are used as lubricants for forming CP titanium tubing at room temperature. Grease with graphite is used as a lubricant for the hot bending of CP titanium tubing but is not recommended for temperatures above 315 °C (600 °F). Phosphate conversion coatings are sometimes used for hot bending of titanium tubing.

# Formability Testing of Sheet Metals

Revised by Michael Miles, Brigham Young University

---

**SHEET METAL FORMING** is the process of converting a flat sheet of metal into a part of desired shape without fracture or excessive localized thinning. The process may be simple, such as a bending operation, or a sequence of very complex operations such as those performed in high-volume stamping plants. In the manufacture of most large stampings, a sheet metal blank is held on its edges by a blankholder ring and is deformed by means of a punch and die. The movement of the blank into the die cavity is controlled by pressure between the upper and lower parts of the blankholder ring.

This control is usually increased by means of one or more sets of drawbeads. These consist of an almost semicylindrical ridge on the upper part of the blankholder and a corresponding groove in the lower part (the positions are sometimes reversed). The drawbeads force the periphery of the blank to bend and unbend as it is pulled into the die; this increases the restraining force considerably. Presses with capacities to 17.8 MN (2000 tonf) are commonly used for the manufacture of large stampings, and presses to 26.7 MN (3000 tonf) are used for heavy-gage parts.

Sheet metal forming operations are so diverse in type, extent, and rate that no single test provides an accurate indication of the formability of a material in all situations. However, knowledge of materials properties and careful analysis of the various types of forming involved in making a particular part are indispensable in determining the probability of successful part production and in developing the most efficient process.

## Types of Forming

Many forming operations are complex, but all consist of combinations or sequences of the basic forming operations—bending, stretching, drawing, and coining (see the section “Forming Processes for Sheet, Strip, and Plate” in this Volume).

**Bending** is the most common type of deformation, and it occurs in almost all forming operations. Bending around small radii can lead to splitting in the early stages of a forming process because it localizes strain and prevents its distribution throughout the part. Ideally, strain

should be distributed as uniformly as possible to maximize the amount of deformation that can be obtained. Even a slight increase in the radius in a given location can sometimes significantly improve strain distribution. Frequently, designs specify smaller radii than necessary, which results in manufacturing problems and increased costs.

Lubrication is not recommended when bending over a sharp radius because die friction reduces strain localization by restricting metal movement away from the radius. The orientation of the sheet in relation to the rolling direction can also be important in a bending operation. During rolling, inclusions and other defects become elongated in the rolling direction, producing lines of weakness. When the axis of bending is in this direction, there is a tendency toward splitting along the lines of weakness. This lowers resistance to fracture compared with when the axis is inclined to the rolling direction. Detailed information on sheet metal lubrication is available in the article “Selection and Use of Lubricants in Forming of Sheet Metal” in this Volume.

The outer and inner panels of a part are frequently assembled by bending (hemming) the edges of the outer panel around the inner panel. This requires material that can be easily bent over very small radii. In the absence of other types of deformation, bending produces tensile stresses on the outside surface. These decrease to zero at an interior level known as the neutral axis. These stresses then become compressive on the inside of the bend. They can cause springback (shape distortion) upon removal of the applied forces. If tensile deformation is also present, the compressive stresses may be reversed, but through-thickness stress and strain gradients generally will still exist.

Many forming operations involve pulling metal over a die radius so that it is initially bent and subsequently straightened. The net strain resulting from this process may be quite small, depending on the size of the die radius and the tensile forces involved. However, the bending and straightening process cold works the metal, particularly at the surfaces, and reduces its subsequent formability.

**Stretching** is caused by tensile stresses in excess of the yield stress. These forces produce biaxial stretching when they are applied in

perpendicular directions in the plane of the sheet. Balanced biaxial stretching occurs when the perpendicular forces are equal. Much higher levels of deformation, as measured by an increase in area, can be reached in balanced biaxial stretching than in any other forming mode.

Many forming operations involve stretching of some areas within the stamping. Automotive outer body panels are typical examples of parts formed primarily by stretching. Parts with regions containing domes, ribs, and embossments also involve stretching.

**Plane-strain stretching** results in elongation in one direction and no dimensional change in the perpendicular direction. It frequently occurs when a wide, flat area of sheet metal is stretched longitudinally—for example, in the sidewall of a stamping. In this case, strain in the transverse direction is prevented by the adjacent metal. Plane-strain stretching is an important type of deformation because most materials fracture at a lower level of strain in plane strain than in any other condition. Many of the fractures that occur in stamping operations are in the plane-strain region.

**Drawing** of sheet metal causes elongation in one direction and compression in the perpendicular direction. The simplest example is the drawing of a flat-bottomed cylindrical cup. In this process, a circular disk is held between two flat annular dies and impacted in the center by a flat-bottomed punch. This draws (pulls) the edges of the disk inward to form the wall of the cup. The metal is stretched radially by the tensile forces produced by the punch, but it is compressed circumferentially as its diameter decreases. Many other forming operations involve substantial drawing.

**Coining** occurs when metal is compressed between two die surfaces. It is used extensively for making coins and parts with similar surface features, for flattening, and for reducing springback upon removal of parts from a die. In many stretching and drawing operations, coining is undesirable because it restricts metal movement, localizes strain, and produces surface damage. Much of the die preparation for these operations concentrates on locating and eliminating coining.

**Combinations of Types of Forming.** Most forming operations involve combinations of

different types of forming. Figure 1 illustrates a part design that requires drawing in the corners; biaxial stretching in the dome; bending, straightening, and plane-strain stretching in the walls; and bending and plane-strain stretching at the tops and bottoms of the walls.

## Formability Problems

The major problems encountered in sheet metal forming are fracturing, buckling and wrinkling, shape distortion, loose metal, and undesirable surface textures. The occurrence of any one or a combination of these conditions can render the sheet metal part unusable. The effects of these problems are discussed next.

**Fracturing** occurs when a sheet metal blank is subjected to stretching or shearing (drawing) forces that exceed the failure limits of the material for a given strain history, strain state, strain rate, and temperature. In stretching, the sheet initially thins uniformly, at least in a local area. Eventually, a point is reached at which deformation concentrates and causes a band of localized thinning known as a neck, which ultimately fractures. The formation of a neck is generally regarded as failure because it produces a visible defect and a structural weakness. Most current formability tests are concerned with fracture occurring in stretching operations.

In shearing, fracture can take place without prior thinning. The most common examples of this type of fracture occur in slitting, blanking, and trimming. In these operations, sheets are sheared by knife edges that apply forces normal to the plane of the sheet. Shearing failures are sometimes produced in stamping operations by shearing forces in the plane of the sheet, but they are much less common than stretching failures.

**Buckling and Wrinkling.** In a typical stamping operation, the punch contacts the blank, stretches it, and starts to pull it through the blankholder ring. The edges of the blank are pulled into regions with progressively smaller perimeters. This produces compressive stresses in the circumferential direction. If these stresses reach a critical level characteristic of the material and its thickness, they cause slight undulations known as buckles. Buckles may develop into more pronounced undulations or waves known as wrinkles if the blankholder pressure is not sufficiently high.

**Fig. 1** Part design requiring a combination of types of forming. B, bending; BS, biaxial stretching; D, drawing; P, plane-strain stretching; U, unbending (straightening). Source: Ref 1

This effect can also cause wrinkles in other locations, particularly in regions with abrupt changes in section and in regions where the metal is unsupported or contacted on one side only. In extreme cases, folds and double or triple metal may develop. These may in turn lead to splitting in another location by preventing metal flow or by locking the metal out. Therefore, increasing the blankholder pressure often corrects a splitting problem.

**Shape Distortion.** In forming operations, metal is deformed elastically and plastically by applied forces. Upon removal of the external forces, the internal elastic stresses relax. In some locations, they can relax completely, with only a very slight change in the dimensions of the part. However, in areas subjected to bending, through-thickness gradients in the elastic stresses will occur; that is, the stresses on the outer surfaces will be different from those on the inner surfaces.

If these stresses are not constrained or “locked in” by the geometry of the part, relaxation will cause a change in the part shape known as shape distortion or springback. Springback can be compensated for in die design for a specific set of materials properties but may still be a problem if there are large material property or process variations from blank to blank.

**Loose metal** occurs in undeformed regions and is undesirable because it can be easily deflected. A phenomenon usually referred to as oil canning, in which a local area can be either concave or convex, can also be encountered. In stampings with two or more sharp bends of the same sign in roughly the same direction, such as a pair of feature lines, a tendency exists for the metal between them to be loose because of the difficulty involved in pulling metal across a sharp radius.

It is sometimes possible to avoid the problem by ensuring that the metal is not contacted by both lines at the same time; thus, some stretching can occur before the second line is contacted (see the article “Press Forming of Coated Steel” in this Volume). There is a tendency for loose metal to occur toward the center of large, flat, or slightly curved parts. Increasing the restraining forces on the blank edges usually improves this condition.

**Undesirable Surface Textures.** Heavily deformed sheet metal, particularly if it is coarse grained, often develops a rough surface texture commonly known as orange peel (see the article “Press Forming of Coated Steel” in this Volume). This is usually unacceptable in parts that are visible in service.

Another source of surface problems occurs in metals that have a pronounced yield point elongation, that is, materials that stretch several percent without an increase in load after yielding. In these metals, deformation at low strain levels is concentrated in irregular bands known as Lüders lines (or bands), or stretcher strains. These defects disappear at moderate and high strain levels. However, almost all parts have some low-strain regions. These defects

are unsightly and are not concealed by painting. Aged rimmed steels and some aluminum-magnesium alloys develop severe Lüders lines.

In some cases, zinc-coated steels exhibit surface defects known as spangles. This phenomenon occurs only in hot-dipped products and is caused by the development of a coarse grain size in the galvanic coating, which makes the individual grains clearly visible. This problem can be corrected in the coating process. In addition to the aforementioned occurrences, handling damage, dents caused by dirt or slivers in the die, and scoring or galling caused by a rough die surface or inadequate lubrication sometimes produce unacceptable surfaces.

## Measurement of Deformation

The principal methods of measuring deformation are gage marks, strain gages, optical extensometers, and thickness and shape measurements.

**Gage Marks.** The most widely used method for measuring deformation is to mark the sheet by etching or scribing or by means of ink, dye, or paint and to measure the changes in the separations of the marks caused by the deformation. Rectangular grid markings and arrays of small-diameter circles (for example, 2.5 mm, or 0.1 in.) are frequently used.

In most production forming operations and in the later stages of tension testing, deformation varies rapidly with location, which can lead to large differences in strain measurements made over different gage lengths. Therefore, small gage lengths, such as the diameters of small, closely spaced circles, are commonly used. Circular markings provide an additional advantage in that it is easy to identify the directions of the maximum (or major) and minimum (or minor) strains and thus to measure their values. Upon deforming, the circles change into ellipses with their major axes in the direction of the maximum strain and their minor axes in the direction of the minimum strain.

This information is essential in determining how close the local strain state is to the maximum the material can withstand without fracturing, which depends on the ratio of the strains. It is also useful in determining how the geometry of a die must be modified when the formability limits of the work material are exceeded.

**Strain Gages and Extensometers.** In some cases, a strain gage or a strain gage extensometer is attached to the sheet or test sample. Accurate strain measurements are thus obtained continuously during a forming operation or test. Optical extensometers, which are particularly effective at high strain rates, can also be used.

**Thickness and Shape Measurements.** Thickness measurements, which can be made rapidly by ultrasonic methods, can sometimes be used to determine strains. In practice, this method is limited to situations in which the ratio of the major and minor strains is known from

previous measurements because many different combinations of strains can lead to the same change in thickness.

Part shape is measured by using templates, checking fixtures, or shadowgraphs or by using a profile meter that employs a stylus to contact the surface. Profile meters may give two- or three-dimensional digital representations of the part. Noncontacting surface digitizers and systems for measuring deformation by locating grid markings in three dimensions are also used.

## Representation of Strain

The most common method of representing strain defines the engineering strain,  $e$ , as the ratio of the change in length,  $\Delta L$ , to the original length,  $L_0$ :

$$e = \frac{\Delta L}{L_0} = \frac{L - L_0}{L_0} = \frac{L}{L_0} - 1 \quad (\text{Eq 1})$$

The second method defines the true strain,  $\epsilon$ , in the region of uniform elongation as the integral of the incremental change in length,  $dL$ , divided by the actual (instantaneous) length,  $L$ :

$$\epsilon = \int_{L_0}^L \frac{dL}{L} = \ln\left(\frac{L}{L_0}\right) = \ln(1 + e) \quad (\text{Eq 2})$$

The engineering strain is easier to calculate and is satisfactory for many applications. The true strain is used in the theoretical analysis of formability and is advantageous in that successive strains can be added to give the cumulative strain.

**The strain state** of a deformed sheet is frequently represented graphically by plotting the maximum or major strain,  $e_1$ , on the vertical axis and the minimum or minor strain,  $e_2$ , which can be positive or negative, on the horizontal axis. This is illustrated in Fig. 2, which shows five strain paths, each leading to the same major strain of 40% but with minor strains ranging from -40 to +40%. The ellipses shown

were originally circles (shown dashed) in the undeformed sheet.

On the right side of Fig. 2, the circles have transformed into ellipses that are larger in all directions than the original circles. This is the region of biaxial stretching and, in the diagonal (45°) direction, of balanced biaxial stretching. In this direction, the circles have expanded without changing shape.

On the left side of Fig. 2, the circles have transformed into ellipses, which are larger in one direction but smaller in the perpendicular direction than the original circles. This is the region of drawing and is the strain state developed in the tension test. On the vertical axis, the ellipses are larger in one direction but unchanged dimensionally from the original circles in the perpendicular direction. This is the region of plane strain.

## Effect of Materials Properties on Formability

The properties of sheet metals vary considerably, depending on the base metal (steel, aluminum, copper, and so on), alloying elements present, processing, heat treatment, gage, and level of cold work. In selecting material for a particular application, a compromise usually must be made between the functional properties required in the part and the forming properties of the available materials. For optimal formability in a wide range of applications, the work material should:

- Distribute strain uniformly
- Reach high strain levels without necking or fracturing
- Withstand in-plane compressive stresses without wrinkling
- Withstand in-plane shear stresses without fracturing
- Retain part shape upon removal from the die
- Retain a smooth surface and resist surface damage

Some production processes can be successfully operated only when the forming properties of the work material are within a narrow range. More frequently, the process can be adjusted to accommodate shifts in work materials properties from one range to another, although sometimes at the cost of lower production and higher materials waste. Some processes can be successfully operated using work material that has a wide range of properties. In general, consistency in the forming properties of the work material is an important factor in producing a high output of dimensionally accurate parts.

## Strain Distribution

Three materials properties determine the strain distribution in a forming operation:

- The strain-hardening coefficient (also known as the work-hardening coefficient or exponent), or  $n$  value
- The strain rate sensitivity, or  $m$  value
- The plastic strain ratio (anisotropy factor), or  $r$  value

The ability to distribute strain evenly depends on the  $n$  value and the  $m$  value. The ability to reach high overall strain levels depends on many factors, such as the base material, alloying elements, temper,  $n$  value,  $m$  value,  $r$  value, thickness, uniformity, and freedom from defects and inclusions.

**The  $n$  value**, or strain-hardening coefficient, is determined by the dependence of the flow (yield) stress on the level of strain. In materials with a high  $n$  value, the flow stress increases rapidly with strain. This tends to distribute further strain to regions of lower strain and flow stress. A high  $n$  value is also an indication of good formability in a stretching operation.

In the region of uniform elongation, the  $n$  value is defined as:

$$n = \frac{d \ln \sigma_T}{d \ln \epsilon} \quad (\text{Eq 3})$$

where  $\sigma_T$  is the true stress (load/instantaneous area) and  $\epsilon$  is true strain, as defined by Eq 2. This relationship implies that the true stress-strain curve of the material can be approximated by a power law constitutive equation proposed in Ref 2:

$$\sigma_T = k\epsilon^n \quad (\text{Eq 4})$$

where  $k$  is a constant known as the strength coefficient.

Equation 4 provides a good approximation for most steels but is not very accurate for dual-phase steels and some aluminum alloys. For these materials, two or three  $n$  values may need to be calculated for the low, intermediate, and high strain regions.

When Eq 4 is an accurate representation of material behavior,  $n = \ln(1 + e_u)$ , where  $e_u$  is the uniform elongation, or elongation at maximum load in a tension test. By definition,  $\ln(1 + e_u)$  is

Fig. 2 Schematic of several major strain/minor strain combinations

identical to  $\epsilon_u$ , which is the true strain at uniform elongation.

Most steels with yield strengths below 345 MPa (50 ksi) and many aluminum alloys have  $n$  values ranging from 0.2 to 0.3. For many higher-yield-strength steels,  $n$  is given by the relationship (Ref 3):

$$n = \frac{70}{(\text{yield strength in MPa})} \quad (\text{Eq 5})$$

A high  $n$  value leads to a large difference between yield strength and ultimate tensile strength (engineering stress at maximum load in a tension test). The ratio of these properties therefore provides another measure of formability.

**The  $m$  value**, or strain rate sensitivity, is defined by:

$$m = \frac{d \ln \sigma}{d \ln \dot{\epsilon}} \quad (\text{Eq 6})$$

A constitutive law that incorporates both strain hardening and strain rate sensitivity is:

$$\sigma_T = k \dot{\epsilon}^n \epsilon^m \quad (\text{Eq 7})$$

A positive strain rate sensitivity indicates that the flow stress increases with the rate of deformation. This has two consequences. First, higher stresses are required to form parts at higher rates. Second, at a given forming rate, the material resists further deformation in regions that are being strained more rapidly than adjacent regions by increasing the flow stress in these regions. This helps to distribute the strain more uniformly.

The need for higher stresses in a forming operation is usually not a major consideration, but the ability to distribute strains can be crucial. This becomes particularly important in the post-uniform elongation region, where necking and high strain concentrations occur. An approximately linear relationship has been reported between the  $m$  value and the post-uniform elongation for a variety of steels and nonferrous alloys (Ref 4). As  $m$  increases from  $-0.01$  to  $+0.06$ , the post-uniform elongation increases from 2 to 40%.

Metals in the superplastic range have high  $m$  values, usually greater than 0.5, which are one to two orders of magnitude higher than typical values for steel. At ambient temperatures, some metals, such as aluminum alloys and brass, have low or slightly negative  $m$  values, which explains their low post-uniform elongation.

High  $n$  and  $m$  values lead to good formability in stretching operations but have little effect on drawability. In a drawing operation, metal in the flange must be drawn in without causing fracture in the wall. In this case, high  $n$  and  $m$  values strengthen the wall, which is beneficial, but they also strengthen the flange and make it harder to draw in, which is detrimental.

**The  $r$  value**, or plastic strain ratio, relates to drawability and is known as the anisotropy factor. This is defined as the ratio of the true width strain to the true thickness strain in the

uniform elongation region of a tension test:

$$r = \frac{\epsilon_w}{\epsilon_t} = \frac{\ln \left( \frac{w}{w_0} \right)}{\ln \left( \frac{t}{t_0} \right)} \quad (\text{Eq 8})$$

The  $r$  value is a measure of the ability of a material to resist thinning. In drawing, material in the flange is stretched in one direction (radially) and compressed in the perpendicular direction (circumferentially). A high  $r$  value indicates a material with good drawing properties.

The  $r$  value frequently changes with direction in the sheet. In a cylindrical cup drawing operation, this variation leads to a cup with a wall that varies in height, a phenomenon known as earing (Fig. 3). It is therefore common to measure the average  $r$  value, or average normal anisotropy,  $r_m$ , and the planar anisotropy,  $\Delta r$ .

The property  $r_m$  is defined as  $(r_0 + 2r_{45} + r_{90})/4$ , where the subscripts refer to the angle between the tensile specimen axis and the rolling direction. The value  $\Delta r$  is defined as  $(r_0 - 2r_{45} + r_{90})/2$ . It is a measure of the variation of  $r$  with direction in the plane of a sheet. The value  $r_m$  determines the average depth (that is, the wall height) of the deepest draw possible. The value  $\Delta r$  determines the extent of earing. A combination of a high  $r_m$  value and a low  $\Delta r$  value provides optimal drawability.

Hot-rolled low-carbon steels have  $r_m$  values ranging from 0.8 to 1.0; cold-rolled rimmed steels range from 1.0 to 1.4, and cold-rolled aluminum-killed (deoxidized) steels range from 1.4 to 2.0. Interstitial-free steels have values ranging from 1.8 to 2.5, and aluminum alloys range from 0.6 to 0.8. The theoretical maximum  $r_m$  value for a ferritic steel is 3.0; a measured value of 2.8 has been reported (Ref 5).

### Maximum Strain Levels: The Forming Limit Diagram

Each type of steel, aluminum, brass, or other sheet metal can be deformed only to a certain level before local thinning (necking) and fracture occur. This level depends principally on the combination of strains imposed, that is, the ratio of major and minor strains. The lowest level occurs at or near plane strain, that is, when the minor strain is zero.

This information was first represented graphically as the forming limit diagram, which

Fig. 3 Drawn cup with ears in the directions of high  $r$  value

is a graph of the major strain at the onset of necking for all values of the minor strain that can be realized (Ref 6, 7). Figure 4 shows a typical forming limit diagram for steel. The diagram is used in combination with strain measurements, usually obtained from circle grids, to determine how close to failure (necking) a forming operation is or whether a particular failure is due to inferior work material or to a poor die design (Ref 8).

For most low-carbon steels, the forming limit diagram has the same shape as the one shown in Fig. 4, but the vertical position of the curve depends on the sheet thickness and the  $n$  value. The intercept of the curve with the vertical axis, which represents plane strain and is also the minimum point on the curve, has a value equal to  $n$  in the (extrapolated) zero thickness limit. The intercept increases linearly with thickness to a thickness of about 3 mm (0.12 in.).

The rate of increase is proportional to the  $n$  value (Fig. 5). The level of the forming limits also increases with the  $m$  value (Ref 4).

The shape of the curve for aluminum alloys, brass, and other materials differs from that in Fig. 4 and varies from alloy to alloy within a system. The position of the curve also varies and rises with an increase in the thickness,  $n$  value, or  $m$  value, but at rates that are generally not the same as those for low-carbon steel.

The forming limit diagram is also dependent on the strain path. The standard diagram is based on an approximately uniform strain path. Diagrams generated by uniaxial straining followed by biaxial straining, or the reverse, differ considerably from the standard diagram. Therefore, the effect of the strain path must be taken into account when using the diagram to analyze a forming problem.

### Materials Properties and Wrinkling

The effect of materials properties on the formation of buckles or wrinkles is the subject of extensive research. In drawing operations, there

Fig. 4 Typical forming limit diagram for steel

is general agreement, based primarily on experiments with conical and cylindrical cups, that a high  $r_m$  value and a low  $\Delta r$  value reduce buckling in both flanges and walls (Ref 10–12). In addition to the aforementioned correlations, a low flow-stress-to-elastic-modulus ratio ( $\sigma_f/E$ ) decreases wall wrinkling (Ref 13). The  $n$  value has an indirect effect. When the binder force is kept constant, the  $n$  value has no effect. However, high  $n$  values enable higher binder forces to be used, which reduces buckling.

In stretching operations, the situation appears to be different. A close correlation between the

formation of buckles at low strain levels and the yield-strength-to-tensile-strength ratio (YS/TS) has been reported, as well as an inverse correlation with the low strain  $n$  value and an absence of correlation with the  $r_m$  value and uniform elongation (Ref 14). Some of the differences between these results may be attributed to the fact that the experiments with cups involved high strains and high compressive stresses, while the stretching experiments were conducted at low strain and low compressive stress levels. In both situations, the problem becomes significantly more severe as the sheet thickness decreases.

### Materials Properties and Shear Fracture

Shear fractures due to in-plane shear stresses are more prevalent in high-strength cold-worked materials, particularly when internal defects such as inclusions are present. Typical strain combinations that cause shear fracture are shown on the forming limit diagram in Fig. 6. For this material, Fig. 6 shows that, at high strain levels in the regions close to  $\epsilon_2 = \pm \epsilon_1$ , failure occurs by shearing before the initiation of necking.

The position and shape of the shear fracture curve depends on the material, its temper, and the

Fig. 5 Effect of thickness and  $n$  value on the plane-strain intercept of a forming limit diagram for low-carbon steel. Source: Ref 9

type and degree of prestrain or cold work (Ref 15–17). Limited data are available on shear fracture.

### Materials Properties and Springback

Materials properties that control the amount of springback that occurs after a forming operation are:

- Elastic modulus,  $E$
- Yield stress,  $\sigma_y$
- Slope of the true stress/strain curve, or tangent modulus,  $d\sigma_T/d\epsilon$

Springback is best described by means of three examples involving a rectangular beam: elastic bending below the yield stress, simple bending with the yield stress exceeded in the outer layers of the beam, and combined stretching and bending. In an actual part, springback is determined by the complex interaction of the residual internal elastic stresses, subject to the constraints of the part geometry.

**Elastic Bending below the Yield Stress.** Tensile elastic stresses are generated on the outside of the bend. These stresses decrease linearly from a maximum at the surface to zero at the center (neutral axis). They then become compressive and increase linearly to a maximum at the inner surface. Upon removal of the externally applied bending forces, the internal elastic forces cause the beam to unbend as they decrease to zero throughout the cross section (Fig. 7a).

The maximum amount of elastic deflection that can be produced without entering the plastic range is proportional to the yield stress divided by the elastic modulus. The strain at the yield point is equal to  $\sigma_y/E$  ( $E = \sigma/\epsilon$ ). The springback moment for a given deflection is therefore proportional to the elastic modulus ( $\sigma = E\epsilon$ ).

**Simple Bending.** In this example, the yield stress is exceeded in the outer layers of the beam. The outer layers deform plastically, and their stored elastic stresses continue to increase, but at a much lower rate that is proportional to the slope of the true stress-strain curve, or tangent modulus,  $d\sigma_T/d\epsilon$ , instead of the elastic modulus. Figure 7(b) illustrates this condition for a beam bent so that 50% of its volume is in the plastic range.

Upon removal of the externally applied bending forces, the stored elastic stresses cause the beam to unbend until their combined bending moment is zero. This produces compressive stresses at the outer surface and tensile stresses at the inner surface.

The springback in this case is less than for a material whose yield strength is not exceeded at the same strain level. This can result from either a higher yield stress or a lower elastic modulus. It is also apparent that higher values of the tangent modulus cause greater springback when the yield strength is exceeded.

In actual conditions, the neutral axis moves inward upon bending because the outer part of the beam is stretched and becomes thinner and because the inner part is compressed and

becomes thicker. This effect is analyzed in detail in Ref 18.

**Combined Stretching and Bending.** In this case, the entire beam can be plastically deformed in tension by as little as 0.5% stretching. However, a stress gradient still exists from the outer to the inner surface (Fig. 7c). Upon removing the external forces, the internal elastic stresses recover.

This causes unbending, but to a lesser extent than in the previous cases. As the level of stretching is increased, the amount of springback decreases because the tangent modulus and therefore the stress gradient through the beam decrease at higher strains. The yield strength ceases to be a factor in springback once all regions are plastically deformed in tension.

In the bending of wide sheets, the metal is deformed in plane strain, and the plane strain properties (elastic modulus, yield stress, and tangent modulus) should be used. The effects of a low elastic modulus and a high yield stress and

tangent modulus in increasing springback have been experienced in forming operations. Springback is more severe with aluminum alloys than with low-carbon steel (1 to 3 modulus ratio). High-strength steels exhibit more springback than low-carbon steels (~2 to 1 yield strength ratio), and dual-phase steels spring back more than high-strength steels of the same yield strength (higher tangent modulus).

The effect of stretching in reducing springback to very low levels has also been reported (Ref 19). Springback is also greatly influenced by geometrical factors, and it increases as the bend angle and ratio of bend radius to sheet thickness increase.

### Effect of Temperature on Formability

A change in the overall temperature alters the properties of the material, which thus affects

Fig. 6 Forming limit diagram including shear fracture. Source: Ref 15

Fig. 7 Springback of a beam in simple bending. (a) Elastic bending. (b) Elastic and plastic bending. (c) Bending and stretching

formability. In addition, local temperature differences within a deforming blank lead to local differences in properties that affect formability.

At high temperatures, above one-half of the melting point on the absolute temperature scale, extremely fine-grain aluminum, copper, magnesium, nickel, stainless steel, steel, titanium, zinc, and other alloys become superplastic. Superplasticity is characterized by extremely high elongation, ranging from several hundred to more than 1000%, but only at low strain rates (usually below approximately  $10^{-2}/s$ ) at high temperatures.

The requirements of high temperatures and low forming rates have limited superplastic forming to low-volume production. In the aerospace industry, titanium is formed in this manner. The process is particularly attractive for zinc alloys because they require comparatively low temperatures ( $\sim 270^\circ\text{C}$ , or  $\sim 520^\circ\text{F}$ ).

At intermediate elevated temperatures, steels and many other alloys have less ductility than at room temperature (Ref 20, 21). Aluminum and magnesium alloys are exceptions and have minimum ductility near room temperature. Alloys of these metals have been formed commercially at slightly elevated temperatures ( $\sim 250^\circ\text{C}$ , or  $\sim 480^\circ\text{F}$ ). The strain rate sensitivity ( $m$  value) and post-uniform elongation for aluminum-magnesium alloys have been found to increase significantly in this temperature range (Ref 22).

Low-temperature forming has potential advantages for some materials, based on their tensile properties, but practical problems have limited application. Local increases in temperature occur during forming because of the surface friction and internal heating produced by the deformation. Generally, this is detrimental because it lowers the flow stress in the area of greatest strain and tends to localize deformation.

A method of improving drawability by creating local temperature differences has been developed and is being used commercially (Ref 23). It involves water cooling the punch in a deep-drawing operation. This lowers the temperature of the blank where it contacts the punch, which is the principal failure zone, and increases the local flow stress. Heating the die in order to lower the flow stress in the deformation zone at the top of the draw wall has also been found to be beneficial. The combination of these procedures has produced an increase of over 20% in the drawability of an austenitic stainless steel.

Fig. 8 Sheet tensile test specimen

## Types of Formability Tests

Formability tests are of two basic types: intrinsic and simulative. Intrinsic tests measure the basic characteristic properties of materials that can be related to their formability. Simulative tests subject the material to deformation that closely resembles the deformation that occurs in a particular forming operation.

**Intrinsic tests** provide comprehensive information that is insensitive to the thickness and surface condition of the material. The most important and extensively used intrinsic test is the uniaxial tension test, which provides the values of many materials properties for a wide range of forming operations. Other commercially important intrinsic tests are the plane-strain tension test, the Marciniak stretching and sheet torsion tests, the hydraulic bulge test, the Miyauchi shear test, and hardness tests.

**Simulative tests** provide limited and specific information that is usually sensitive to thickness, surface condition, lubrication, and geometry and type of tooling. This information usually relates to only one type of forming operation. Many simulative tests, such as the Olsen and Swift cup test, have been used extensively for many years with good correlation to production in specific cases. Several simulative tests are described later in this article.

## Uniaxial Tension Testing

The most widely used intrinsic test of sheet metal formability is the uniaxial tension test. A specimen such as that illustrated in Fig. 8 is used; its sides are accurately parallel over the gage length, which is usually 50.8 mm (2.00 in.) long and 12.7 mm (0.50 in.) wide. The specimen is gripped at each end and stretched at a constant rate in a tension machine until it fractures, as described in ASTM E 8. The applied load and extension are measured by means of a load cell and strain gage extensometer.

The load extension data can be plotted directly. However, data are usually converted into engineering (conventional) stress,  $\sigma_E$

Fig. 9 Typical engineering and true stress-strain curves

(load/original cross section), and engineering strain,  $e$  (elongation/original length), or to true stress,  $\sigma_T$  (load/instantaneous cross section), and true strain,  $\epsilon$  (natural logarithm of strained length/original length).

In addition, for formability testing, it is common practice to measure the width of the specimen during the test. This is done either intermittently by interrupting the test at pre-selected elongations to make measurements manually or continuously by means of width extensometers. From these measurements, the plastic strain ratio (anisotropy factor), or  $r$  value, can be determined.

During the rolling process used to produce metals in sheet form and the subsequent annealing, the grains and any inclusions present become elongated in the rolling direction, and a preferred crystallographic orientation develops. This causes a variation of properties with direction. Therefore, it is common practice to test specimens cut parallel to the rolling direction and at  $45^\circ$  and  $90^\circ$  to this direction. These are known as longitudinal, diagonal, and transverse specimens, respectively. This also enables the values of  $r_m$  and  $\Delta r$  to be calculated. Because the mechanical properties and elongation tend to be lower in the transverse direction, tests in this direction are often used as the basis for specifications.

The rate at which the test is performed can have a significant effect on the end results. Two methods are commonly used to determine this effect. In the first method, replicate samples are tested at different rates, and the results are influenced by variations between the samples. In the second method, the test rate is alternated between two levels. This approach avoids the problem of variation between samples, but it cannot be used at very high rates and is complicated by transients, which occur each time the rate is changed. The strain rate sensitivity, or  $m$  value, can be calculated from these tests.

Figure 9 shows a typical engineering stress-strain curve and the corresponding true stress-strain curve for a material that has a smooth transition between the very low strain (elastic) and the higher strain (plastic) regions of the curve. When the load is removed in the elastic

region, the sample returns to its original dimensions. When this is done in the plastic region, the sample retains permanent deformation.

In the tension test, the load increases to a maximum value and then decreases prior to fracture. The decrease is due to the localization of the deformation, which causes a reduction in cross section. This reduction has a greater effect than the opposing increase in flow stress due to strain hardening.

### Test Procedure

For accurate and reproducible results, uniaxial tension testing must be performed in a carefully controlled manner. The main steps in the procedure are discussed in detail in the article "Uniaxial Tension Testing" in *Mechanical Testing and Evaluation*, Volume 8 of *ASM Handbook*. These procedures are summarized next.

**Specimen Preparation.** The surfaces of the specimen should be free from scratches or other damage that can act as stress raisers and cause early failure. The edges should be smooth and free from irregularities. Care should be taken not to cold work the edges, or to ensure that any cold work introduced is removed in a subsequent operation, because this changes mechanical properties and lowers ductility.

It is common practice to mill and grind the edges, but other procedures such as fine milling, nibbling, and laser cutting are also used. When a new method is used, initial tests should be performed to compare the results with those obtained by conventional methods.

The width of a nominally 12.7 mm (0.50 in.) wide specimen should be measured to the nearest 0.025 mm (0.001 in.), and the thickness for specimens in the range of 0.5 to 2.5 mm (0.02 to 0.1 in.) should be measured to the nearest 0.0025 mm (0.0001 in.). If this is impractical because of surface roughness, the thickness should be measured to the nearest 0.025 mm (0.001 in.).

The tension test is sensitive to variations in the width of the specimen, which should be accurately controlled. For a specimen 12.7 mm (0.50 in.) wide, the width of the reduced section should not deviate by more than  $\pm 0.25$  mm ( $\pm 0.01$  in.) from the nominal value and should not differ by more than  $\pm 0.05$  mm ( $\pm 0.002$  in.) from end to end.

Some investigators intentionally taper the reduced section slightly toward the center to increase the probability that fracture will occur within the gage length. In this case, the center should not be narrower than the ends by more than 0.10 mm (0.004 in.).

**Alignment of Specimens.** The specimen should be accurately aligned with the centerline of the grips. The effect of small displacements (10% of the specimen width) of one or both ends from the centerline has been calculated (Ref 24). It has been determined that the latter case is the more serious, but both strongly affect the strain in the outermost fibers. It has also been concluded that the calculated stress-strain curve is not significantly affected at strains above 0.3%.

**Measurement of Load and Elongation.** The applied load is measured by means of a load cell in the test machine, for which the usual calibration procedures must be followed (ASTM E 4). Elongation is usually determined by using a clip-on strain gage extensometer (ASTM E 83). In addition, small scratches are often scribed across the specimen at the ends of the gage length so that the total elongation can be determined from the broken specimen.

Circle grids are sometimes etched or printed on the specimen. These can be used to measure the strain distribution and width strain as well as the overall strain. This can be done continuously by means of a video camera and data processing system if required. Optical extensometers are used for some applications, particularly high-speed testing. These units require well-illuminated boundaries that are clearly delineated by means of high-contrast coatings, such as black-and-white paint.

An approximate measure of elongation can be obtained from the crosshead travel. This involves errors due to elongation of the specimen outside the gage length and elastic strain in the grips, which can be compensated for to some extent. This method is used when the specimen is inaccessible, such as in nonambient testing.

The signals from the load cell and extensometer can be plotted on a chart recorder or processed by a data processing system to the required form, such as plots of stress versus strain or tables of mechanical and forming properties.

**Measurement of Width and Thickness.** In addition to the initial measurements of specimen

width and thickness, which are required to calculate the stress, measurements can be made at intervals during the test to determine the  $r$  value (ASTM E 517) and to determine the reduction in area and true strain. The  $r$  value is measured at a specified strain level between the yield point and the uniform elongation (for example, at 15% elongation). It can be measured by stopping the test at this strain level and then measuring the width accurately ( $\pm 0.013$  mm, or  $\pm 0.0005$  in.) at a minimum of three equally spaced points in the gage length (for a 50.8 mm, or 2.0 in., gage length). In practice, the thickness is calculated from the specimen width and length, assuming no change in volume.

Alternatively, width measurements can be made during the test using width extensometers, although this is a more complicated procedure. Attempts are underway to develop combined width and length extensometers to simplify this method.

Reduction in area is the ratio  $(A_0 - A)/A_0$ , where  $A$  is the instantaneous cross-sectional area and  $A_0$  is the original cross-sectional area. It is used to calculate the true strain in the region of post-uniform elongation. A large reduction in area at fracture correlates with a small minimum bend radius and high energy absorption. To calculate the reduction in area, the width and thickness must be measured in the narrowest part of the necked region.

**Effect of Gage Length on Elongation.** In post-uniform elongation, part of the specimen is elongated uniformly, and the remainder is narrowed into a necked region of higher strain level. A change in the gage length alters the ratio of these two regions and has a significant effect on the total elongation measurement. This phenomenon is discussed in detail in Ref 25.

To obtain results that are comparable for different gage lengths, the ratio of the square root of the cross-sectional area to the length,  $\sqrt{A/L}$ , should be the same. When comparing samples of different thickness, this implies that the gage length or the width should be adjusted to maintain this ratio.

**Rate of Testing.** Most tension tests are performed on screw-driven or hydraulic testing machines at strain rates of  $10^{-5}$  to  $10^{-2}$  s $^{-1}$ . The strain rate is defined as the increase in length per unit length per second. These tests are known as low strain rate or static tests.

**Table 1 Typical tensile properties of selected sheet metals**

Material	Young's modulus, $E$		Yield strength		Tensile strength		Uniform elongation, %	Total elongation, %	Strain-hardening exponent, $n$	Average normal anisotropy, $r_m$	Planar anisotropy, $\Delta r$	Strain rate sensitivity, $m$
	GPa	$10^6$ psi	MPa	ksi	MPa	ksi						
Aluminum-killed drawing quality steel	207	30	193	28	296	43	24	43	0.22	1.8	0.7	0.013
Interstitial-free steel	207	30	165	24	317	46	25	45	0.23	1.9	0.5	0.015
High-strength low-alloy steel	207	30	345	50	448	65	20	31	0.18	1.2	0.2	0.007
Dual-phase steel	207	30	414	60	621	90	14	20	0.16	1.0	0.1	0.008
301 stainless steel	193	28	276	40	690	100	58	60	0.48	1.0	0.0	0.012
409 stainless steel	207	30	262	38	469	68	23	30	0.20	1.2	0.1	0.012
3003-O aluminum	69	10	48	7	110	16	23	33	0.24	0.6	0.2	0.005
6009-T4 aluminum	69	10	131	19	234	34	21	26	0.23	0.6	0.1	-0.002
70-30 brass	110	16	110	16	331	48	54	61	0.56	0.9	0.2	0.001

Most high-volume production forming operations are performed at considerably higher strain rates—in the range of  $1$  to  $10^2 \text{ s}^{-1}$ . To determine the tensile properties in this range, dynamic test machines, which operate at rates of  $10^{-1}$  to  $10^2 \text{ s}^{-1}$ , are used (Ref 25). As mentioned previously, steels have higher tensile properties and lower elongations at high strain rates. The properties of aluminum alloys have little sensitivity to the strain rate.

## Materials Properties

The stress-strain curve determined by uniaxial tension testing provides values of many formability related materials properties. Several of these properties and methods for measurement are discussed subsequently. Table 1 lists typical values of properties measured in tension tests on thin (0.5 to 1.0 mm, or 0.02 to 0.04 in.) sheet materials.

**Young's Modulus.** The initial slope of the stress-strain curve, that is, the ratio of the stress to the strain in the elastic region before any plastic deformation has occurred, is the Young's modulus,  $E$ , of the material. This property affects springback and shape distortion at low strains. For accurate measurement of Young's modulus, a low strain rate and a high data acquisition rate should be used in the elastic region (below approximately 0.5% elongation), and a very stiff tension-testing machine should be used if strain is inferred from crosshead displacement.

**Yield Strength.** The stress at which the stress-strain curve deviates in elongation from the initial elastic slope by a specified amount, commonly 0.2%, is known as the yield strength (YS). The yield strength determines the load necessary to initiate deformation in a forming operation, which is usually a high percentage (40 to 90%) of the maximum load required.

For accurate measurement of yield strength, a rate of loading of less than 690 MPa/min (100 ksi/min) is specified. Beyond this point, the strain rate should not exceed  $0.08 \text{ s}^{-1}$ . Some materials elongate without an increase in load, or at a decreased load, at the transition between the elastic and plastic regions. The point at which this initiates is known as the yield point.

With a decrease in load, the material has an upper yield point and a lower yield point. The upper yield point is difficult to measure reproducibly. The lower yield stress usually fluctuates, and the minimum value is used.
